The observed adsorption heat thus varies about a mean value of about 18 k. Cals. in Series (a) and 17 k. Cals. in Series (b); the limits of accuracy of the method (measured by the deviation, in individual determinations, from this mean) is approximately of the same order as for the vacuum calorimeter previously used.<sup>9</sup> There was, as before, no indication of a definite decrease or increase of the adsorption heat with an increase in the adsorbed concentration. The value previously found by the vacuum calorimeter method for the adsorption of hydrogen on platinum black in approximately the same condition was about 17 k. Cals. or, in some cases, less; and, in view of the experimental difficulties which attend the direct measurement of adsorption heats, including the possible variation in the heat value with the state of the platinum, a greater degree of reproducibility is not probable. It may be noted, further, that, in all cases, the rapid adsorption of only a small volume of gas by a relatively large mass of platinum is involved: accordingly, the heat measured is principally, if not exclusively, that of the primary adsorption.

Measurements were now carried out with ethylene, for which the vacuum calorimeter is inapplicable. The presence of residual adsorbed hydrogen leads, as already stated, to too high apparent heats of adsorption; and the value of *Q* gradually fell from slightly over 30 k. Cals. to a constant value of about 9 k. Cals. as the residual hydrogen was removed. The higher apparent values include heat of reaction in addition to heat of adsorption. The approximate constancy of the adsorption heat after this preliminary stage of hydrogen removal has been passed is shown in Table IV. Pure ethylene, undiluted with an inert gas, was used throughout. A few comparative tests, not included in the table, were, however, made with ethylene-helium mixtures—in which case the adsorption of ethylene was, of course, considerably smaller—and were found to give similar heat values.

The heat effect observed in measurements Nos. 6 and 9 of the above series is considerably below the average (about 9 k. Cals.), but has been

<sup>9</sup> *J. Chem. Soc.*, 1931, 3313.

included for completeness of record. The platinum was in every case previously degassed for 12 hours at  $100^{\circ}$ , save before measurement No. 11, for which the degassing temperature was  $200^{\circ}$ . Over 95 per cent. of the total adsorption observed during the period of each heat measurement (5 minutes) occurred in the first 2 minutes. All determinations were at  $18^{\circ}$ .

### Summary.

The secondary adsorption of ethylene by platinum black, namely the slow process which takes place subsequently to the almost immediate primary adsorption, follows the relationship previously observed by Ward for hydrogen on copper, according to which the ratio of the volume adsorbed to the square root of the time is a constant. It consequently also agrees with Bangham and Burt's general equation, which involves a linear relationship between  $\log v$  and  $\log t$ .

Since the normal vacuum calorimetric method is inapplicable to ethylene, on account of its small adsorption at low pressures, a calorimetric method involving adsorption at atmospheric pressure has been developed for the measurement of the adsorption heat. This was tested for hydrogen diluted with an inert gas, and was found to give an adsorption heat of approximately the same value as that previously determined in the normal way. On applying the method to ethylene, a molecular heat of adsorption of about 9 k. Cals. was observed. It is necessary in all cases, both for the measurement of the kinetics and of the heat of adsorption, to subject the platinum to preliminary treatment to remove residual adsorbed gases other than ethylene.

## THE COLLISION MECHANISM AND THE PRIMARY PHOTOCHEMICAL PROCESS IN SOLUTIONS.

By E. RABINOWITCH AND W. C. WOOD.

*Received 28th May, 1936.*

### (1) The Collision Number and the Collision Intervals.

The mean *number of collisions*,  $z$  (gas), of a gas molecule under NTP conditions is of the order of  $10^{10}$  per second. The average *duration of a collision*,  $\tau$ ,—i.e. the time during which the interaction energy is not small compared to  $kT$ —is about  $10^{-13}$  to  $10^{-12}$  secs. The order of magnitude of  $\tau$  is the same for collisions of saturated molecules and those of free atoms or radicals. Only collisions of complicated particles possessing many degrees of freedom and low frequencies corresponding to the interchange of energy between them, can last for longer than  $10^{-12}$  secs.

The average *collision interval*  $\theta$  (gas) (because of the smallness of  $\tau$ ) is practically equal to  $1/z$  (gas).

We now consider collisions between the molecules of a *solute* (not their collisions with the molecules of the solvent), and compare them with the collisions of the same molecules in the gaseous state. In the case of a strong interaction between solute and solvent, leading to the formation of solvates or of clusters of solvent molecules surrounding the dissolved particles, all the three quantities  $z$ ,  $\tau$  and  $\theta$  may be affected by dissolution.

In the case of a weak interaction, as presented for instance by solutions of permanent gases, or of iodine in carbon tetrachloride, the average values of  $z$ ,  $\tau$  and  $\theta$  may remain practically unchanged. The collision duration  $\tau$ , in particular, must remain unaffected by the presence of the solvent, if the interaction of the colliding particles and their kinetic energy are independent of the solvent. If, in addition, the solvation energy of a colliding pair (Fig. 1a), is not different from that of the two separated particles (Fig. 1b), then the probability of finding two given molecules in the state of collision must be the same in the gaseous and in the dissolved state. The aggregate time spent by a molecule in the collision-state during a second will therefore be the same in both cases. This total collision-time is equal to  $z\tau$ . With  $(z\tau)_{\text{(sol)}} = (z\tau)_{\text{(gas)}}$  and  $\tau_{\text{(sol)}} = \tau_{\text{(gas)}}$ , the collision number  $z_{\text{(sol)}}$  must be equal to  $z_{\text{(gas)}}$  as well.

The purpose of this paper is to show that even in this ideal case of a solution which leaves the average values of  $z$  and  $\theta$  unchanged, the *distribution* of collisions is changed in a significant manner. In a gas, the actual values of the collision-intervals are distributed according to the usual statistical law, the probability of an interval  $\theta$  being proportional to  $e^{-\theta}$ . In a closely-packed medium, *the collisions occur in sets*. The

FIG. 1.

intervals  $\theta$  between the collisions belonging to one set are very short, while those  $\Theta$  between the sets are correspondingly longer. If the average number of collisions in a set is  $\bar{n}$ , then the average length of the inter-set intervals must be  $\Theta = \bar{n}\theta_{\text{(gas)}}$ , in order that the total collision number  $z$  may remain unchanged.

The occurrence of collision-sets is due to the fact that the colliding pair of particles is surrounded by the molecules of the solvent and can escape from this "cage" only by a process of diffusion during which it has an opportunity of colliding several times.

To illustrate this consequence of a high concentration of the molecules in a solution, we constructed a simple model, shown schematically in Fig. 2. It consists of a flat brass plate (1) with a zig-zag border (2), and an insulated knob (3) in the centre. The knob is connected to one pole of the battery, the plate itself to the other pole. A number (20-60) of small balls are distributed on the plate. All but one of them are insulated, and represent the molecules of the solvent. The one non-insulated ball and the central knob represent two dissolved molecules; every time they come into contact (as shown in the figure) a circuit is closed and the collision registered by a lamp or by an electro-magnetic recording mechanism on a drum.

The plate is placed on a shaking machine and the balls brought into strong agitation. The zig-zag border aids in transforming the regular movement of the machine into a chaotic agitation of the balls. Fig. 3 shows two sections of the recording; Fig. 3a was made with 25 balls on the plate; Fig. 3b with 50 balls. The "intermittent" character of the collision mechanism at high densities is clearly shown by this figure. Table I. gives the results of registering the collisions for about 10 mins. at different densities. Column (1) shows the number of the insulated balls; column (2) the proportion of the surface covered by the balls; column (3) the average number of collisions per second. Column (4), which contains the average number of collisions per set, is illustrated by Fig. 4. A comparison of columns (4) and (5) shows that *whereas the total number of collisions ( $z$ ) remains practically unchanged, the average length of the series ( $\bar{n}$ ) increases very sharply after a certain density has been exceeded.*

FIG. 2.

The addition of one ball to 51 causes the trebling of  $\bar{n}$ , without producing any change in  $z$ .

It is, of course, only with the greatest caution that the quantitative results obtained with this two-dimensional macroscopic model may be

FIG. 3a.

FIG. 3b.

used for real three-dimensional molecular systems. It is, however, safe to assume that in these systems also, the average length of the collision-sets increases very sharply at higher densities. The essential question is: to what section of the curve in Fig. 4 does the real liquid correspond?

If we consider, for instance, liquid argon with a molecular weight about 40 and a density 1.4, we find that 1 c.c. contains about  $1.9 \times 10^{23}$  molecules. The volume of an argon molecule is about  $1.3 \times 10^{-23}$  c.c.; the total volume of the molecules contained in 1 c.c. of the liquid is thus

0.25 c.c. In the case of  $\text{CCl}_4$ , to take another example,  $6 \times 10^{21}$  molecules are contained in 1 c.c. of the liquid, with an aggregate volume of about 0.35 c.c. A volume density of 35 per cent. occupied space corresponds to a two-dimensional density of about 50 per cent. occupied surface. This density produces, according to our experiments, collision-sets with an average length of about 2. This estimate of the average length of collision-sets in real solutions is confirmed by considerations of the diffusion coefficients. According to Einstein and Smoluchowski the mean displacement  $\Delta$  of

FIG. 4.

coefficient  $D$  by the equation

$$\bar{\Delta}^2 = 2Dt \quad (1)$$

In a liquid, even a displacement over a distance equal to a single molecular diameter (say  $\Delta = 3 \times 10^{-8}$  cm.) is achieved on a complicated zig-zag path consisting of a great number of single segments. The statistical

equation (1) can therefore be applied even to such small displacements. The diffusion coefficients of uncharged molecules in solutions of low viscosity (e.g. of iodine in carbon tetrachloride) are of the order of  $2 \times 10^{-5}$ . Inserting this value of  $D$  into (1) and assuming  $\Delta = 3 \times 10^{-8}$  we obtain :—

$$t = 2.5 \times 10^{-11} \text{ secs.}$$

During this interval, the collision partners are agitating to and fro in a narrow space, without separating themselves so far as to allow a molecule of the solvent to slip between them. A gas molecule travelling at a speed  $10^4$  cm./sec. would cover a similar path,  $3 \times 10^{-8}$  cm., in  $3 \times 10^{-12}$  secs. The above calculated "separation interval,"  $2.5 \times 10^{-11}$  secs. is ten times longer and will allow the particles to collide more than once, but probably not more than four or five times.

We may thus assume that collision-sets actually occur in solutions, but are on the average rather short, consisting of 1, 2 or 3 collisions. As confirmed by Table I., the probability of a collision-set consisting of  $n$  collisions is proportional to  $e^{-an}$ , where  $a$  is a constant depending on the density; single collisions are therefore the most frequent at all densities. Longer sets may occur in systems with higher density: highly viscous liquids, glasses or true solid phases.

The influence of the collision-sets upon the velocity of bimolecular thermal reactions was already discussed in a paper by Weiss.<sup>1</sup> The existence of collision-sets tends to slow down the reaction rate; but its influence can become appreciable only if the activation energy is very small—so small that the proportion  $1/x$  of the number of collisions in which this energy is attained is greater than  $1/\bar{n}$ . In this case, the molecules which have to wait  $\bar{n}$  times longer than in a corresponding gas for their first collision, are unable to make use (statistically speaking) of all the  $\bar{n}$  collisions forming the set, because they react already after the first  $x$  collisions. For all bimolecular reactions of which the velocity can be studied experimentally,  $x$  is, however, of an order much higher than 10, and no effect of the "intermittency" of collisions can therefore be observed, at least in ordinary non-viscous solutions. In highly viscous systems the reaction velocity can be expected to decrease because of an effect of this kind.

A process in which the influence of the intermittent character of the collision-mechanism is very important is the quenching of fluorescence in liquids, because this reaction often occurs at the very first collision of the activated molecule with an appropriate partner. Wawilow and Franck<sup>2</sup> have discussed the problem of the quenching of fluorescence in solution and the influence of the viscosity from this point of view, connecting the efficiency of the quenching to the time which the quenching molecule needs to diffuse towards the activated molecule. The problem of the coagulation of sols by electrolytes was earlier treated in the same way by Smoluchowski.<sup>3</sup> In both these cases the essential problem can be formulated as follows. At the beginning of an interval, the particles are distributed at random; how long would it take them to collide for the first time? In this paper, we are interested also in another side of the problem: supposing that the molecules are in a state of collision at the beginning of an interval—how long would it take them to reach a random

<sup>1</sup> J. Weiss, *Naturwiss.*, 1935, 23, 229.

<sup>2</sup> S. I. Wawilow, *Z. Physik*, 1929, 53, 665; J. M. Franck, S. I. Wawilow, *ibid.*, 1931, 69, 100.

distribution? The case of "photochemical equilibrium" which is discussed in the next section, is one in which both sides of the intermittent collision-mechanism play an important rôle.

## (2) The Primary Photochemical Process in Solution.

Atoms or radicals formed by photochemical dissociation in solution—e.g. by a process  $A_2 + h\nu \rightarrow A + A$ —are, immediately after their formation, in the same position as two dissolved particles after a collision. They are in touch with each other and imprisoned in a "cage" of solvent molecules. It was pointed out in a previous paper<sup>4</sup> that this situation offers the possibility of an immediate recombination of the dissociation products, called "primary recombination" to distinguish it from the "ordinary" recombination of atoms or radicals distributed at random throughout the whole body of the gas or solution. The primary recombination tends to decrease the quantum yield of dissociation below unity. Its occurrence is obviously connected with the intermittent collision mechanism discussed in Part I. If the mean number of collisions forming a set is  $\bar{n}$ , then the probability of a molecule-pair separating before a second collision has taken place is  $1/\bar{n}$ . It is often assumed that free atoms or radicals recombine at their first triple collision in gases, and at the very first collision in a liquid phase. Under these circumstances the probability of a freshly-formed atom-pair escaping primary recombination must be equal to  $1/\bar{n}$ , and the quantum yield of dissociation  $\gamma = 1/\bar{n} < 1$ . On the other hand, the intervals between the sets being  $\bar{n}$  times longer than the average collision intervals  $\theta_{(gas)}$  in a corresponding gas, the mean "expectation of life" of an actually separated atom-pair will be  $n\theta_{(gas)}$ . The stationary concentration of the free atoms in the illuminated solution is given by the product of the velocity of their production and their mean life-time. The first being proportional to  $\gamma = 1/\bar{n}$ , and the second to  $\bar{n}$ , the concentration itself becomes independent of the occurrence of primary recombination, i.e. of the existence and length of the collision-sets. The kinetics of all photochemical reactions of which the velocity is proportional to the concentration of free atoms is therefore unaffected by primary recombination, and no hints as to the amount of primary recombination, can be obtained from experiments in which the stationary concentration of free atoms is measured.

This conclusion is based on the assumption that the state of the atoms or radicals formed by light absorption is not essentially different from that of the same particles meeting accidentally in solution. This is not always the case. In the above mentioned paper<sup>4</sup> the *kinetic energy* of the dissociation products was considered to be essential. The absorbed light practically never exactly corresponds to the convergence limit of the band spectrum. The dissociation products possess therefore a kinetic energy in excess of the average thermal energy at room temperature. We suggested that this excess-energy makes the photochemical dissociation "explosive" and permits the products to break through the surrounding "walls" of the liquid and thus escape recombination. According to the law of conservation of momentum, however, this reasoning is correct only for the case of the dissociation products being heavier than the molecules of the solvent. Otherwise, the dissociation products, however high their kinetic energy may be, are stopped or reflected back by the first collision with a molecule of the solvent. A dependence of the primary recombination upon the amount of excess

<sup>4</sup> J. Franck, E. Rabinowitch, *Trans. Faraday Soc.*, 1934, **30**, 120.

energy—i.e. upon the wave-length of the absorbed light—may thus be expected especially in the case of solvents with very light molecules—for instance, water. As a matter of fact, a strong dependence of the quantum yield on wave-length is often observed in aqueous solutions.

In the case of a solution of iodine in carbon tetrachloride, however, no such effect of the wave-length can be anticipated, because the mass of the dissociation product ( $I = 127$ ) is less than that of the solvent ( $CCl_4 = 156$ )

We have already applied this conclusion<sup>5</sup> to show that neither the absolute value of the stationary concentration of free iodine atoms in illuminated iodine solutions in carbon tetrachloride and hexane, nor their independence on wave-length can be used as an argument against the occurrence of primary recombination in these solutions.

One may think that the excited electronic state  $^2P_{1/2}$  of one of the iodine atoms formed photochemically may prevent it from primary recombination. No decrease in the quantum yield was, however, observed at wave-lengths longer than 5000 Å., i.e. in a region where the absorbed energy becomes insufficient to produce an excited iodine atom.

### Summary.

1. Under certain conditions the duration of a single collision and the probability of finding two given molecules in a state of collision is the same for two molecules in solution as well as in gaseous state.

2. In this case, the total number of collisions  $z$  between dissolved molecules and the average collision interval  $\theta$  are also unchanged by dissolution.

3. Even in these "ideal" solutions, an important change takes place concerning the distribution of the collision-intervals. *The collisions occur in sets.* The same two molecules collide several times before separating, and this collision-set is followed by a correspondingly longer "inter-set interval."

4. A mechanical model was constructed which shows the rapid increase of the average length of the sets with growing concentration of the particles. It is plausible that in ordinary non-viscous solutions the average length of the sets is of the order of 2 or 3 collisions per set—an estimate which is in agreement with the magnitude of the diffusion coefficients.

5. With average sets of  $\bar{n}$  collisions each, the probability of a colliding pair separating before a second collision takes place is  $1/\bar{n}$ . For atoms or radicals formed by photochemical dissociation in solution, this means a quantum yield of dissociation  $\gamma = 1/\bar{n} < 1$ . This decrease of the quantum yield by "primary recombination" is, however, exactly compensated by an increase in the mean life-time of free atoms (which is equal to the "inter-set interval"). The stationary concentration of atoms or radicals in an illuminated solution is therefore independent of the occurrence of primary recombination.

6. The kinetic energy of the products of photochemical dissociation can help them to escape primary recombination only if their mass is much larger than that of the molecules of the solvent. This is the case in some aqueous solutions, but not for instance in that of iodine in  $CCl_4$  (which has been the object of our experimental investigations).

Our thanks are due to Professor F. G. Donnan, F.R.S., for the opportunity he gave us to work in this laboratory and for his kind interest in our work.

# CATALYTIC INTERCHANGE OF HYDROGEN WITH WATER AND ALCOHOL.

BY D. D. ELEY AND M. POLANYI.

*Received 29th May, 1936.*

## 1. Introduction.

In conjunction with the first observation of J. Horiuti and Polanyi of the atomic interchange between hydrogen and water occurring in the presence of platinum black,<sup>1</sup> it was noticed that the addition of acids increased the rate of reaction, while the addition of alkali causes it to slow down.<sup>2</sup> The effect of alkali is especially pronounced in the atomic interchange between hydrogen and alcohol, the rate of which is reduced four-fold by addition of *N/10* KOH.

Since these effects of the nature of the solution on the rate of exchange were found to be reversible, it was concluded that the nature of the solution was exercising a genuine influence on the rate of atomic interchange and that the rate-determining factor must be one in which hydrogen ions are formed. Assuming that the reaction proceeded in two steps

the authors concluded that it is the second step which determines the reaction rate.

Further results<sup>3</sup> supported these considerations, proving (a) that the first order rate (*k*) of interchange in alkaline alcoholic solutions depended on the hydrogen pressure (*p*) as  $k \propto \frac{1}{p^{0.5}}$ ; and (b) that the effect of temperature on the rate corresponds to an activation energy of about 10,000 cal. Both (a) and (b) show that the rate measured is not determined by the diffusion of the hydrogen to the catalyst<sup>4</sup> and in addition the relationship  $k \propto \frac{1}{p^{0.5}}$  seemed to indicate a preliminary equilibrium  $\text{H}_2 + 2\text{Pt} \rightleftharpoons 2(\text{PtH})$  to be present corresponding to the first step of the above scheme.<sup>5</sup>

More strength seemed to be added to this conclusion when it was further observed that the inverse proportionality of *k* to the square root of pressure also holds for the enzymatic interchange between hydrogen and water. It was then suggested to measure the rate of the "first step" by the use of the parahydrogen conversion and the  $\text{D}_2 + \text{H}_2 = 2\text{HD}$  reaction.<sup>6</sup>

<sup>2</sup> *Ibid.*, 931.

<sup>3</sup> Horiuti and Polanyi, *Proc. Manchester Lit. Phil. Soc.*, 1934, 70, 47.

<sup>4</sup> See discussion, p. 1397.

<sup>5</sup> A considerable amount of experimental work developing these observations has been carried out in this laboratory by Professor J. Horiuti. We understand that Professor Horiuti will publish these results in the near future.

<sup>6</sup> Bottomley, Cavanagh and Polanyi, *Nature*, 1935, 136, 103.

The present paper presents some observations carried out on this line, using a mixture of *parahydrogen* and deuterium and following the conversion of the *para*- $H_2$  and the interchange of the deuterium in the same experiment. A similar technique has been successfully used simultaneously by A. Farkas in a series of catalytic experiments about which a preliminary announcement has been recently made. A. Farkas used *orthodeuterium* and observed the spin conversion and the interchange after the experiment. Two of his observations bear directly on our subject. He found absence of spin conversion when a sample of *ortho*-deuterium was contacted with water containing a platinum catalyst, while at the same time part of the deuterium was replaced by hydrogen. The same result was found with a bacterial emulsion. Farkas concludes from these observations that the atomic exchange is in both cases an ionisation process.<sup>6</sup>

## 2. Experimental Technique.

The atomic interchange was set up and controlled in the same way as in the earlier investigations of Horiuti and one of the authors.<sup>1,2,3</sup> Since this technique has not yet been described we will indicate its main points.

FIG. 1.

A quartz vessel (S in Fig. 1), which, including the tubing up to the taps  $T_1$  and  $T_2$ , had a volume of 110 cc., was attached to a vacuum apparatus by two standard ground joints  $G_1$  and  $G_2$ , which formed a bearing for shaking the vessel in a plane perpendicular to the paper. The vessel

<sup>6</sup> We cannot comment on these experiments as we do not know their exact details. However, we would draw attention to the fact that, when the solution is not shaken, there is a strong probability that the diffusion of gas to the catalyst governs the rate. In this event the result reported by Farkas would still be obtained, while it would have no bearing on the true reaction mechanism. We wish to acknowledge the courtesy of Dr. A. Farkas, who, knowing we were engaged in this work, has refrained from investigating the problem any further.

was immersed in a Dewar vessel containing ice, or water the temperature of which was kept constant by a cooling spiral or a heating coil wound around the neck of the vessel S (see Fig. 2). The temperature of the bath was measured by a thermocouple, indicated in Fig. 1.

The platinum catalyst (carefully washed with the solution under examination) was placed in the reaction vessel and 10 c.c. of the liquid (*i.e.* water or alcohol or a solution made up with these liquids) was added. The system being then evacuated the mixture of para-hydrogen (in the earlier experiments, normal hydrogen) and deuterium was introduced from the storage bulb  $B_1$ , by means of the Toepler pump  $T_1$  through the liquid air trap  $U_1$ , and the total pressure read on the manometer  $M_1$ . The vapour pressure of the liquid was subtracted from this reading to give the pressure of hydrogen in the reaction vessel. The shaking was done by the pull of

FIG. 2.

a string from a motor-driven eccentric, the usual frequency of 15-20 vibrations per second being controlled by the tension in the springs  $f_1$  and  $f_2$ , which were fixed to a frame. The hydrogen was introduced through tap  $T_1$  after steady shaking had been reached, the letting-in of the hydrogen taking only about three

seconds. A similar time was required to remove the greater part of the hydrogen through  $T_1$  by means of the diffusion pump  $P_1$  into the evacuated three-litre bulb  $B_2$ . The gas was then circulated through the liquid air trap  $V$  by means of  $P_1$  for thirty minutes to remove all traces of vapour, and then either burnt in a copper-oxide furnace or expelled into an evacuated bulb attached to the ground-joint  $G_4$ . In the first case the water so obtained was distilled and analysed for deuterium by the micropycnometer method<sup>7</sup>—(this was the procedure in the earlier experiments not using parahydrogen)—in the second case the bulb was removed to the thermal conductivity apparatus and analysed by the method of A. and L. Farkas for para-hydrogen and deuterium content.<sup>8</sup> Some practical modifications of this method which were used in the measurements are described in a supplementary paper by Eley and Tuck.<sup>9</sup>

### 3. Preparation of Materials.

**Ethyl Alcohol.**—The aldehyde was removed by refluxing with KOH, and after distillation it was refluxed with quick-lime. Distillation off fresh quick-lime gave alcohol with less than 0.3 per cent. water content.

**Hydrochloric Acid.**—I.C.I. chemically pure HCl was diluted and twice distilled, the constant boiling mixture so obtained being diluted as required.

**Caustic Potash Solutions.**—Merck's pure KOH was used.

formaldehyde, according to Houben-Weyl II (*Zweite Auflage*), p. 496. One gram of  $PtCl_4$  at a time was so treated and the platinum black so obtained was divided up by pipetting its suspension in water. One-sixteenth of the yield was the quantity usually used in the exchange experiments, and according to calculation it equals 0.3 gm., assuming the yield equals 100 per cent. The pipetting method was found to give a moderately accurate division of the platinum black.

The conditions under which the various experiments have been conducted are given in the Tables. The Roman numerals I, II, etc., refer to the "batch" of catalyst (obtained from 1 gm.  $PtCl_4$ ), while the small letters *a*, *b*, etc., refer to particular specimens obtained by subdivision of the batch. Care has been taken in the investigation of all effects of pressure, temperature, etc., to keep check on the activity of the catalyst by inserting experiments under a fixed set of conditions between individual members of a series under varied conditions. Wherever the catalyst has been "disturbed," *e.g.* in changing from one solution to another, the authors have assured themselves as to the reversibility of the effect by returning to the original system. The order in which the experiments have been done may be seen from the dates given in the tables.

## 4. Experimental Results.

In the Tables \* the first order velocity constants of the atomic interchange,  $k_D = \frac{1}{t} \cdot 2.3 \log \frac{C_0^D}{C_t^D}$  are given in  $\text{min.}^{-1}$ , and, where *para*-hydrogen

was used, the first order constants  $k_P = \frac{1}{t} \cdot 2.3 \log \frac{C_0^P}{C_t^P}$  are also given.

$C_0$  and  $C_t$  are the deuterium (D) or *para*-hydrogen (P) contents at the beginning and end of the experiment, respectively. We proceed in our report by commenting on successive parts of the Tables.

Table I. shows the reproducibility of  $k_D$  when the reaction is repeated on one day several times. In Table II. it is shown that  $k_D$  increases with decrease of pressure in a manner similar to that shown in earlier experiments with heavy hydrogen and alcoholic potash. The data can be approximated by  $k_D \propto \frac{1}{p^{0.33}}$  as shown in Fig. 3.

A brief discussion of the part played by the purely physical processes of dissolution and diffusion in determining the reaction rate might be given here. The rate at which hydrogen is dissolved certainly does not retard the reaction to any noticeable degree since we found that by using a large amount of catalyst (0.24 grm.) the velocity of conversion and interchange could be increased to much higher values than those quoted in the Tables. In two experiments made with aqueous N HCl we found

The part played by the process of diffusion of the hydrogen to the catalyst cannot be eliminated completely but our main conclusions are not affected by this uncertainty. Taking constant quantities of catalyst the diffusion rate should not be affected by the HCl or KOH added to the solvent, and the rate expressed in a first-order constant should be independent of pressure while its temperature coefficient should be mainly that of the solubility of hydrogen divided by the viscosity.

It follows that variations found in the reaction rate caused by the addition of HCl or KOH to the solution are due to genuine alterations of the reaction rate and that where the reaction is considerably slowed down, the influence of diffusion will be negligible. It follows further that any variation of  $k_D$  or  $k_P$  with pressure indicates genuine alterations in reaction rate, and here again, the slower

\* In the Tables  $E_D$  is the activation energy in calories for the interchange reaction, calculated from the temperature coefficient of the velocity constants according to the equation of Arrhenius.  $E_P$  is the same quantity for the *para*-hydrogen conversion.

reactions (*i.e.* those at the high pressure end), can be only slightly influenced by the diffusion process.

If the rate of diffusion were governing the reaction velocity, the constants  $k_D$  and  $k_T$  would have a small temperature coefficient corresponding to activation energies of 3400 cal. for both water and alcohol. Since the measured activation energies are in excess of these values we may again conclude that the influence of diffusion is not predominant. These arguments could be amplified further, but we feel that, taken in conjunction with the evidence presented in Section 5, they form a safe basis for our later conclusions.

Table III. shows that  $k_D$  is about four times smaller in aqueous  $N/10$  KOH than in aqueous  $N$  HCl.

Table IV. gives extensive evidence on the activation energy of atomic interchange in aqueous solutions.

of the reaction  $H_2 + D_2 \rightarrow 2HD$ . We can, therefore, assume that the parahydrogen conversion and the interchange are both due to the same reaction, while attributing the ratio  $k_D/k_T$  to the higher rate of reaction of  $H_2$  as compared with  $HD$ .

\* In these experiments a mixture of 6 per cent. HD molecules and about 35 per cent.  $pH_2$  was used.

The same conclusion can be drawn from the data of the next section, referring to alcoholic solutions. In the course of these experiments the dependence of the reaction rate on pressure and on temperature has been re-examined, to link up our results with previous experiments and with the extensive unpublished work of Professor Horiuti. We found that our system behaved in a similar manner to those observed previously. The rate observed in alcoholic potash decreases with increasing pressure (Table VI.b), the observations being best represented (Fig. 4) by  $k_D \propto \frac{1}{p^{0.6}}$ . The activation energy of the interchange reaction (Table VI.c) observed in the same solution gives an average of 8500 cal. which is definitely higher than in aqueous solutions, though somewhat lower than the previously observed value of 10,200 cal.

FIG. 4.\*

\* Note added in proof.—In Fig. 4 the average of Expts. 83, 85, 86 and 91 is taken as  $k_D = 0.0011$ . Actually it is  $k_D = 0.00118$ , and the true point is somewhat lower. The correction is within the exptl. error, and does not affect our statement.

In none of the experiments recorded in Table VI. is there an excess of *parahydrogen* conversion over the interchange reactions which goes beyond the factor 2-3 found in aqueous solutions. The ratio  $k_p/k_D$  is, indeed, mostly near to unity. We can offer no explanation for the variations of  $k_p/k_D$ , some of which might be attributed to experimental errors.

Our main conclusion is that variations in  $k_p$  are mainly parallel to variations in  $k_D$ , over the whole range of about 100-fold variations of  $k_D$  caused by concurrent changes in the nature of the liquid, the pressure and the temperature, and including (in the case of catalyst III in the experiments recorded in Tables VI.b, VI.c) some poisoning of the catalyst. Our present methods cannot be used to follow any wider variations of the reaction rate.

### 5. Comparison of the Foregoing Results with the Atomic Interchange of Hydrogen with Benzene.

Any suspicion that an actual excess of the rate of *parahydrogen* conversion over the rate of interchange above the normal factor might be concealed by some unknown feature of our experimental technique seems to be removed by the following

\* In these experiments a mixture of 6 per cent. HD molecules and about 35 per cent. *p*H<sub>2</sub> was used.

† The large (12-fold) increase in velocity constant observed here appears to be due to activation of the Pt black on admission of air. It would appear that the reduction of PtO<sub>2</sub> by H<sub>2</sub> at 200° C. has yielded a preparation less active than that obtained by HCHO. This action of air is borne out by the fact that admission of air to Pt black (prepared with formaldehyde) often leads to a transient increase in catalytic activity.

observations on the system  $H_2 + 0.03$  gram. Pt black (IIb) + 10 c.c. benzene.<sup>12</sup> In two experiments we found:—

Partial Pressure of $H_2$ in mm.	$T^\circ C.$	$t$ mins.	$k_p$	$k_D$
47	19	32	0.079	0.0029
120	19.5	12.5	0.065	0.0024

The *parahydrogen* conversion is found to go 20-30 times as fast as the interchange. This result confirms the assumption made previously<sup>12</sup> that the dissociation of  $H_2$  into atoms is faster than the interchange with benzene. At the moment we only wish to emphasise the fact

that we have here obtained a considerable excess of *parahydrogen* conversion over the interchange reaction, thus proving that our experimental procedure does detect an excess when it is present.

We restrict ourselves to a quite provisional statement of the theoretical implications of our results, because other lines of investigation carried on in this laboratory, especially by the use of polarised metal surfaces, indicate that the phenomenon of ionisation is too complex to be interpreted on the evidence of our experiments only.

<sup>12</sup> Compare Horiuti, Ogden and Polanyi, *Trans. Faraday Soc.*, 1934, **30**, 663.

<sup>13</sup> Horiuti and Polanyi, *Trans. Faraday Soc.*, 1934, **30**, 1164.

Since the rate of *parahydrogen* conversion is 2-3 times in excess of the interchange rate between HD and water or alcohol we assume that the conversion is essentially the same process as the interchange, the rate being somewhat higher because  $H_2$  reacts more quickly than HD. There is no evidence of a preliminary equilibrium  $H_2 \rightleftharpoons 2H$  corresponding to the "first step" in the mechanism quoted in our introduction. In consequence, the rate-determining process must be the splitting of the  $H_2$  molecules. This splitting is influenced by the nature and acidity of the liquid, which leads us to the conclusion that the products of the  $H_2$  dissociation (or, more exactly, the transition state leading to them) are profoundly influenced in their energy by electrostatic interaction with the ions of the liquid. These products, therefore, cannot be homopolar H atoms but must be H ions or alternatively H atoms in a strongly polarised state, *e.g.* participating in a strongly polar Pt—H bond.

The previous interpretation of the pressure dependence  $k_D \propto \frac{1}{p^n}$  where  $n$  is about 0.5 can no longer be upheld. This function should be explained as resulting from the adsorption isotherm of the  $H_2$  molecules (or, more accurately, of the molecules in the transition state) and not as the equilibrium constant of the reaction  $H_2 \rightleftharpoons 2H$ .\*

Finally, it is interesting to note the relationship between reaction rate and activation energy when comparing  $N$  HCl and  $N/10$  KOH solutions, in water. The reaction rate in the former is about 4 times greater than in the latter, while the activation energy is about 1600 cal. smaller for the slower reaction. The variation in the reaction rate is thus seen to be dominated by the changes in the temperature independent factor. A similar effect has been observed by Professor Horiuti for the addition of KOH to 98 per cent.  $C_2H_5OH + 2$  per cent.  $H_2O$ .

\* Reference should be made to the recent paper of J. Horiuti and G. Okamoto (*Scientific Papers of the Institute of Physical and Chemical Research of Japan*, 28, 231), which contains a preliminary report on interchange reactions catalysed by an anodically polarised nickel sheet and details of measurements of the electrolytic separation factor of H and D on cathodes consisting of various metals. Horiuti suggests some new concept of the processes involved, which we will discuss at a later stage of this enquiry.

## THE ELECTROLYTIC DISSOCIATION OF HEAVY WATER.

By W. F. K. WYNNE-JONES.

*Received 8th June, 1936.*

In a preliminary communication<sup>1</sup> it was reported that the ionic product of heavy water is about one-third that of ordinary water: the work has now been brought to a conclusion and the revised value for the ratio is  $1/5$ .

The method employed is to measure the e.m.f. of cells of the type

<sup>1</sup> Topley and Wynne-Jones, *Nature*, 1934, 134, 574.

Such cells of course give rise to a liquid junction potential, but the uncertainty of this is not sufficient to make the results unreliable and there is much evidence that when the liquid junction is properly controlled data obtained by this method agree excellently with those from methods which have the theoretical advantage of avoiding liquid junctions. As Guggenheim<sup>2</sup> has pointed out, the e.m.f. of a cell with liquid junction can be written

$$E = E_{\text{El}} + E_{\text{S}} + E_{\text{D}}$$

where  $E_{\text{El}}$  is the difference of the electrode potentials,  $E_{\text{S}}$  is a "salt effect" and  $E_{\text{D}}$  is the diffusion potential calculable by the equations of Planck and Henderson.  $E_{\text{S}}$  cannot be unambiguously separated from  $E_{\text{El}}$  but it will vanish at infinite dilution and may therefore be eliminated by extrapolation. In a cell of the type used here both  $E_{\text{S}}$  and  $E_{\text{D}}$  are small since the solutions in the two halves of the cell are practically identical.

The greatest difficulty encountered in the work was the preparation of the solutions since the amount of heavy water available, though large for this substance, was insufficient for the use of ordinary volumetric and analytical methods: the method finally adopted was to add weighed amounts of concentrated solutions of acid and alkali in ordinary water to weighed amounts of heavy water.

Since the final concentrations of acid and alkali were small, the percentage of light water introduced by this procedure did not exceed 0.2 per cent.

As it is of interest to compare all the thermodynamic properties relative to dissociation and not merely the free energy change, it was decided to measure the temperature coefficient of the dissociation constant and measurements were made at 15°, 25° and 35°.

### Experimental.

The electrical equipment consisted of a Queen potentiometer with which readings could be made directly to 0.02 millivolt, a Leeds and Northrop high sensitivity galvanometer of 570 ohms resistance, and a standard cell which was repeatedly checked against a set of standards belonging to Professor G. A. Hulett. The apparatus was all placed on an equipotential shield as recommended by White.<sup>3</sup> The potentiometer was calibrated by the makers and checked during the course of the work.

Three thermostats were used and the temperatures which were constant to 0.01°, were read on thermometers which had been originally calibrated at the Physikalische Reichsanstalt and rechecked at the Bureau of Standards; the ice points of these thermometers were determined during the course of this work and the appropriate corrections applied to the readings.

The cells were made in one piece with a suitable arrangement of taps so that the liquid junctions could be made in the manner proposed by Unmack and Guggenheim<sup>4</sup> and without exposure to the atmosphere. Each half-cell contained about 3 c.c. of solution and the liquid junction required about 2 c.c. The cells were of Pyrex glass except for the tubes carrying the electrodes; these tubes, however, did not come into contact with the solutions. It was found possible to make measurements on one cell successively at the three temperatures without the necessity of bubbling hydrogen at each temperature: this was effected by making

<sup>2</sup> Guggenheim, *J. Physic. Chem.*, 1930, **34**, 1758.

<sup>3</sup> White, *J. Amer. Chem. Soc.*, 1914, **36**, 2011.

<sup>4</sup> Unmack and Guggenheim, *Det. Kgl. Dansk Vid. Selsk.*, 1930, **10**, 8.

the first measurement at the lowest temperature, closing the taps connecting the liquid junctions before transferring to the next thermostat and at intervals momentarily opening the taps connecting the saturated KCl bridge and the hydrogen electrodes to the atmosphere. Cells treated in this way agreed to a tenth of a millivolt with cells equilibrated in the usual way. All cells kept constant in e.m.f. to 0.05 millivolt for at least 1 hour after the liquid junctions were made.

The hydrogen electrodes were made of platinum foil covered with a black deposit according to the instructions of Popoff, Kunz and Snow.\* Before a measurement with heavy water the electrodes were dried with filter paper and washed with a few drops of the solution to be used in the cell.

The hydrogen (protium) gas was obtained from a cylinder and was passed through a tube containing active copper at 500°; the deuterium was prepared from pure D<sub>2</sub>O in an electrolytic generator which had previously been run for a sufficient length of time to get rid of traces of light hydrogen.

The acid solutions were made up from constant-boiling hydrochloric acid; about 0.01 gm. of acid was introduced into a special flask and sufficient KCl added to make the required ionic strength; about 10 c.c. of heavy water were then distilled directly into the flask and its amount determined by weighing. The alkaline solutions were similarly prepared from a concentrated solution of NaOH which was standardised against the constant boiling acid. In the earlier experiments the acid and alkali were weighed directly in the vessel used for the solutions but it was found to be both quicker and more accurate to use a micro-pipette of the type devised by Linderström-Lang and Holter;† such a pipette can easily be made to deliver 0.01 c.c. with an accuracy of 0.2 per cent.

The heavy water was prepared electrolytically and found by Dr. P. W. Selwood to have a density of 1.1079 at 25°; it was distilled in a current of nitrogen consecutively from alkaline permanganate and barium oxide in an all-glass apparatus, the final distillation being direct into the weighing flask. The density of the water after it had been in use for a month was 1.1070.

### Results.

In Table II. are given the values of the negative logarithms of the ionic products of  $H_2O$  and  $D_2O$  at zero ionic strength; these values are obtained by extrapolation and are expressed in

volume concentration units (moles per litre).

### Discussion of Results.

For convenience in calculation the concentrations have been expressed as gram-molecules per 1000 grams of solution; for the final values of the ionic product however transposal to volume units has been made by multiplying by the square of the density of water,  $H_2O$  or  $D_2O$ , at the temperature of measurement. There is usually some ambiguity in the significance of free energy differences when the solvent is changed and Bell<sup>7</sup> has pointed out that it is impossible to decide the units in which the concentrations should be expressed; here, however, the ambiguity is slight since owing to the virtual identity of the molar volumes of  $H_2O$  and  $D_2O$  the free energy difference is the same whether the concentrations are expressed in mol. fractions or in volume units.

The values of the ionic product at zero concentration have been obtained by plotting  $-\log K + 2A\sqrt{\mu}$  against  $\mu$ ;  $K$  is the ionic product at the ionic strength  $\mu$  and  $A$  is the constant of the Debye-Huckel expression and is equal to  $\frac{2.954 \times 10^6}{(DT)^{3/2}} \cdot \sqrt{2d}$ . The values of  $A$  employed

are given below: for their computation the data of Lewis and Macdonald<sup>8</sup> for the expansion of  $D_2O$  and of Lewis, Olson and Maroney<sup>9</sup> for the dielectric constants were used.

In Fig. 1 are plotted the values of  $\log K$  against  $1/T$  and the data of Harned and Hamer<sup>10</sup> for ordinary water are included.

The difference in the slopes of the curves for  $H_2O$  and  $D_2O$  corresponds to a difference of 940 Cals. in the heats of ionisation of these compounds whereas the difference in their free energy of ionisation is 970 Cals.; it is evident that the entropies of ionisation must be practically identical. If we assume exact equivalence of the changes in free energy and heat of ionisation, we can represent the dissociation constant and the heat of ionisation of heavy water by equations similar to those used by Harned and Hamer, altering only the first term to correspond with the difference in the heats of ionisation of ordinary and heavy water

$$\log K = -4787.3/T - 7.1321 \log T - 0.010365T + 22.801$$

$$\Delta H = 21,926 - 14.812T - 0.04746T^2.$$

<sup>7</sup> Bell, *J. Chem. Soc.*, 1932, 2905.

<sup>8</sup> Lewis and MacDonal, *J. Amer. Chem. Soc.*, 1933, **55**, 3957.

<sup>9</sup> Lewis, Olson and Maroney, *J. Amer. Chem. Soc.*, 1933, **55**, 4731.

<sup>10</sup> Harned and Hamer, *J. Amer. Chem. Soc.*, 1933, **55**, 2194.

These equations are, however, cumbersome in use and necessitate elaborate tables for their accurate application since ordinary temperatures are far removed from the absolute zero; we have therefore preferred to represent our results by the equations

$$\text{H}_2\text{O. } \log K = 14.000 - 0.0331 (t^\circ - 25) + 0.00017 (t^\circ - 25)^2$$

$$\Delta H = 13,450 - 42.8 (t^\circ - 25)$$

$$\text{D}_2\text{O. } \log K = 14.71 - 0.03544 (t^\circ - 25) + 0.00017 (t^\circ - 25)^2$$

$$\Delta H = 14,420 - 42.8 (t^\circ - 25).$$

FIG. 1.

These equations are, of course, purely empirical interpolation formulæ but they reproduce the data of Harned and Hamer with an accuracy of about 1 per cent. within the range  $0^\circ$  to  $50^\circ$  C.

It should be noted that the difference in the heats of ionisation of  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  is determined with greater accuracy than would appear from the possible errors in the dissociation constants. This is because the change in the dissociation of water with temperature can be evaluated directly from the temperature coefficient of the acid-base cell without a knowledge of the concentrations, and the liquid junction potentials are substantially independent of the temperature. We are thus able to say that the error in the difference  $(\Delta H_{\text{D}_2\text{O}} - \Delta H_{\text{H}_2\text{O}})$  is probably less than 50 calories.

Abel, Bratu and Redlich<sup>11</sup> have recently published the results of a determination of the ionic product of heavy water using a cell without liquid junctions. They developed a very elegant micro-technique which enabled them to work with much smaller quantities than were employed in this work. Their results which were obtained mainly at 21° refer to mixtures of H<sub>2</sub>O and D<sub>2</sub>O and by extrapolation they de-

FIG. 2.

duced that the ratio of  $K_w$  for H<sub>2</sub>O and D<sub>2</sub>O is 6.27; on the assumption that the ratio is the same at 25° their value of  $K_w$  for D<sub>2</sub>O at 25° would be  $1.6 \times 10^{-15}$ ; however, their results are expressed in molalities and in order to convert to the volume concentration scale we must multiply by  $(1.1079)^2$ , i.e., 1.227; their value

then becomes  $1.96 \times 10^{-15}$ , in excellent agreement with ours.

In Fig. 2 are shown the data of Abel, Bratu and Redlich for mixtures of H<sub>2</sub>O and D<sub>2</sub>O. The ionic equilibria in these mixtures are quite complicated since there are two forms of hydroxyl ion, three forms of water and four of the hydroxonium ion; nevertheless the almost linear relationship between  $\log K_w$  and the mol. fraction of heavy water suggests that the energies of ionisation form an arithmetic series.

### Summary.

The dissociation of heavy water has been determined from measurements of electromotive force at 15°, 25° and 35°. At 25° the ionic product of heavy water is  $1.95 \times 10^{-15}$  while that of ordinary water is  $1.0 \times 10^{-14}$ . From the temperature coefficient the heat of ionisation is calculated to be 940 calories greater than that of ordinary water and this difference exactly accounts for the difference in the ionic products.

This work was carried out at Princeton University, New Jersey, and was begun in collaboration with Mr. B. Topley of University College, London: unfortunately, owing to Mr. Topley's departure from Princeton, the work had to be completed without the advantage of his co-operation. The inception of the work was due to him and his help in the early stages was invaluable.

I also wish to express my thanks to Professor H. S. Taylor, F.R.S., for his great kindness in placing the resources of the Frick Chemical Laboratory at my disposal, and to the Leverhulme Trustees for the award of a fellowship.

# MIGRATION OF CAESIUM ON TUNGSTIC OXIDE.

BY L. FRANK.

*Received 12th June, 1936.*

## § 1. Introduction.

There has recently been much investigation of the photo-electric properties of monomolecular films of alkali metals on semi-conducting surfaces (such as oxides, salts, etc.), but comparatively little is known about the adsorption process itself. Though this adsorption may of course differ widely for different bases and alkali metals we might expect to find some features of a general nature, the differences being more or less quantitative.

The starting-point of this paper was an observation made in this laboratory, that a surface of iron oxide as is used in a Kunsman source became photo-electric when bombarded with caesium atoms and that the total photo-electric effect decreased with time after cessation of the bombardment. Various reasons might be ascribed as the cause of this decay, *e.g.*, the deposition of layers of gas on the surface, or the re-evaporation of the alkali metal; this paper shows, however, that this phenomenon can only be satisfactorily explained on the assumption of a migration of the caesium into the mass of the oxide. This adsorption is here investigated in some detail.

A similar process of migration has been suggested by Bosworth<sup>1</sup> to explain the decline in the photo-electric effect of sodium and potassium layers on tungsten, and it is not surprising to find that, in our case too, the process takes an appreciable time at room temperature. Bosworth found that the tungsten strip he employed did not act as continuous substrate but had a large capacity for sodium, due, he suggests, to cracks and imperfections which give the metal a sponge-like structure and permit the diffusion of the alkali metal into the body of the strip. Thus, the effective area for adsorption is many times the geometrical surface of the strip. We should expect a surface of tungstic oxide to be even more sponge-like than a strip of tungsten; indeed Powell and Mercer<sup>2</sup> were compelled to assume such a structure in order to explain their results on the positive ion emission from indium and thallium layers on tungstic oxide. These authors, however, found that little migration into the oxide took place below 400° C.

This work deals with the adsorption of caesium on tungstic oxide as prepared by Powell and Mercer.<sup>2</sup> This oxide was found to be more convenient to handle than iron oxide, upon which preliminary observations were made and it gives very similar results.

The photo-electric effect is taken as a measure of the concentration of caesium on the outermost surface of the oxide.

## § 2. Preliminary Experiments.

An oxidised tungsten strip (1 mm. wide, 0.07 mm. thick) was bombarded with caesium atoms from a molecular gun, arranged so that only the central part of the strip (1 cm. long) was struck by caesium atoms. This part was found to become photo-electrically active, the oxide itself being inactive. The maximum yield was in the ultraviolet region and a mercury arc was therefore used as a convenient light source in all subsequent experiments. A spot of light (2 mm.  $\times$  1 mm.) was focussed on the strip by a quartz lens; it entered the experimental tube through a quartz window. The lamp was moved parallel to the strip and a distribution of the photoelectric effect (as measured by a Compton electrometer) was obtained. This could be regarded qualitatively as a measure of the surface concentration of caesium at the different points. Fig. 1 in which the relative photocurrents are plotted against the length of the filament

FIG. 1.—Distribution of photo-electric current along the strip.

represents such a distribution at one stage during the bombardment. The photoelectric activity is seen to be restricted to that part of the strip actually struck by caesium atoms.

When the bombardment was stopped the activity was found to decay over the period of hours, as in the experiments of Bosworth. Traversing the strip with a spot of light, however, showed that no appreciable spreading of the patch occurred during the decay, thus proving that this decay was not due to a migration of the caesium over the superficial surface of the oxide.

This process of depositing caesium and letting it decay was repeated many times without removing the caesium that had already decayed, and each time a careful search was made for any spreading effect, which, however, did not occur. The decay could be speeded up by heating the strip, but this also did not produce any spreading of the patch.

It was therefore clear that if the decay was due to an adsorption process it would have to be explained in this case by a migration of caesium into the mass of the oxide. This hypothesis is quite reasonable, because the concentration gradients into the body of the oxide are much steeper than any along the length of the strip. Experience gained during these preliminary experiments led to the construction of apparatus permitting an investigation of the migration over a wide temperature range of the oxide.

## § 3. The Apparatus.

In the final form of the apparatus the caesium atoms are supplied by a molecular gun, so arranged that the beam of atoms falling on the oxide surface could be interrupted at will. A bulb into which caesium had been distilled is shown at the bottom of Fig. 2; it is provided with a pinhole P, 1.5 mm. in diameter, into which a steel ball fits loosely. By controlling the position of the ball magnetically, the atomic beam incident upon the pinhole may, with great efficiency,\* be started or stopped instantaneously. The beam is defined by this pinhole and the stop H of 2.2 mm. diameter. By cooling the stop with liquid

\* Blank experiments showed that the beam intensity dropped to about one part in 100 within a few seconds after closing the pinhole and to less than one part in 1000 in a few minutes if in addition the oven was removed from the caesium bulb.

air, any scattering or re-evaporation of caesium there is prevented. An intermediate stop S is inserted to prevent excessive accumulation of caesium in the upper part of the gun. This type of molecular gun was first described by Brady.<sup>3</sup> The beam then strikes a tungsten strip F (1 mm. wide and 0.07 mm. thick supported on heavy copper leads L, passing into the tube on copper-pyrex seals) which can be heated electrically or cooled by immersing the copper leads in liquid oxygen. Any temperatures above 125° K. can thereby be attained. The temperature of the strip is determined by a Pt-Pt Rh thermocouple (gauge 48) spot-welded to the centre of the strip. The strip is surrounded by a cylindrical nickel electrode E, slotted parallel to its axis, to admit light and also the caesium beam. The light enters the tube through a small quartz window W, stuck on the pyrex flange with stove enamel and baked in air at 220° C. before assembly. A platinised guard ring R, provides electrostatic shielding for the tube. The outside is shielded by covering with earthed tinfoil.

FIG. 2.—Apparatus.

A platinised guard ring R, provides electrostatic shielding for the tube. The outside is shielded by covering with earthed tinfoil.

#### § 4. Preparation of Caesium.

Caesium was made (a) from a mixture of caesium chromate and Misch-metal heated by electron bombardment, or (b) by heating a mixture of caesium chloride and calcium in a high vacuum and sealing off into a series of ampoules after repeated distillation. The contents of one of these, broken magnetically, is distilled into the bulb of the molecular gun while the pinhole is closed by the steel ball. No difference was found in the behaviour of caesium from the two sources.

#### § 5. Determination of the Beam Intensities.

It is well known from the work of Langmuir and Kingdon<sup>4</sup> that if caesium atoms strike a hot clean tungsten filament, or a filament which has a monomolecular layer of oxygen on its surface, the atoms will stick for a time and then be re-evaporated as positive ions. The tungsten strips employed here behaved similarly, in spite of their massive coat of oxide. Over the range of beam intensities used a filament temperature of 600° C. was sufficient to ionise all the caesium atoms in the beam, as was proved by the fact that variation of the temperature of the strip on either

<sup>3</sup> Brady, *Physic. Rev.*, 1932, 41, 613.

<sup>4</sup> Langmuir and Kingdon, *Proc. Roy. Soc., A*, 1924, 107, 61.

side of 600° C. made no difference to the ionic current drawn to the collecting electrode.

This observation provided a very convenient and accurate method of measuring the total amount of caesium deposited during a run. The oven temperature was allowed to become steady, the pinhole was opened and the molecular beam allowed to fall upon the red-hot strip. The total number of atoms falling on the strip per sec.,  $n$ , is given by

$$n = i/10e$$

where  $i$  is the steady ionic current in amps. It is then a simple matter of geometry to calculate the number of atoms/cm.<sup>2</sup>/sec. at the point where the observations of the photo-electric effect are made.

If caesium atoms are allowed to fall on the strip, the total amount deposited can be determined by flashing it to a high temperature and plotting positive ion current against time. By graphical integration of this curve the total quantity of electricity emitted by the strip is obtained and thence the total number of positive ions emitted. From the work of Langmuir and Kingdon, and of Powell and Mercer <sup>2</sup> we should not expect any emission of neutral atoms of caesium from the strip for low concentrations of caesium at strip temperatures below those at which there is no detectable ionic current. In agreement with this it was found that within the limits of experimental accuracy, the total amount of caesium deposited on the strip in any experiment was equal to the amount which could be re-evaporated by the method just described. This was true for all concentrations of caesium employed, the total number of atoms deposited varying from  $10^{14}$  to  $10^{16}$  atoms/cm.<sup>2</sup> at all temperatures at which the decay phenomena were studied (below 130° C.).

It is clear then that no re-evaporation of caesium atoms from the surface occurs at the temperatures at which the decay phenomena are studied.

We have, thus, two alternative ways of determining the total amount of caesium deposited during a given experiment: Either to measure the ionic current produced by allowing a steady molecular beam to fall upon the red-hot oxidised strip and thus deduce the number of incident atoms/cm.<sup>2</sup>/sec., calculating from this the amount deposited in a given time. Or to remove the caesium at the end of the experiment and estimate the total amount from the integrated emission. The second method was chosen as being the more convenient.

## § 6. Experimental Procedure.

The strip was oxidised as described by Powell and Mercer.<sup>2</sup> The thickness of the oxide film was of the order of  $10^{-4}$  cm. The apparatus was baked out as well as the presence of the quartz window would permit, all metal parts being thoroughly outgassed. A pressure within the limits  $2 \times 10^{-7}$  to  $8 \times 10^{-8}$  mm. Hg (measured by an ionisation gauge) was obtained in the tube which was continuously pumped out by a mercury diffusion pump through a wide lead and a liquid air trap.

Before performing any experiment the oxidised strip was freed from traces of alkali introduced during manufacture or preliminary handling, since these traces of alkali produce a positive ion emission in addition to that due to the incident beam of caesium atoms. The strip was therefore glowed at 700° C. and a potential of 60 volts applied between it and the collector, so as to eliminate the contaminating ions, the treatment being continued until the thermionic emission from this cause was immeasurable. An ampoule containing caesium was broken and the caesium distilled into the bulb from a side tube (not shown) while the pin-hole was closed. The side tube was then sealed off and the caesium distilled on to the strip by surrounding the bulb with a cylindrical electric oven. An additional heater wound directly on the glass prevented condensation

of caesium near the pin-hole. The temperature of the oven was measured by a Pt-Pt Rh thermocouple. A spot of light from the mercury arc was focussed on the centre of the strip which was also the centre of the caesium beam.

### § 7. Standard Experiment.

The strip at + 60 volts was first kept at 600° C., a temperature sufficient to keep it clean from caesium. The heating current being then cut off, the strip was cooled to the temperature at which the adsorption was to be studied, while the caesium in the furnace reached temperature equilibrium. After reversing the potential to accelerate photo-electrons towards the collector, the pin-hole was opened and the photo-emission measured during the deposition of caesium as a function of time at a fixed spot of the strip. After a given time the beam was cut off by closing the pin-hole and removing the oven surrounding the caesium bulb. Observations of the now diminishing photo-electric emission were continued. After an appropriate time the field was reversed again, the strip flashed to 600° C., so that the deposited caesium was emitted thermionically and the beam intensity computed by the method given in § 5.

### § 8. Experimental Results.

#### (a) Deposition at Room Temperature.

Fig. 3 shows two characteristic curves of rise and decay of photo-electric effect.

Curve (a) shows the result of a deposition of  $1.6 \times 10^{15}$  atoms/cm.<sup>2</sup> in 8 minutes; the effect rises continuously until the beam is cut off, after which it decays to a small fraction within a few hours. Curve (b) is a similar result for a smaller beam intensity; not only is the rise here less rapid but a greater deposit is required to produce the same photo-electric intensity. Moreover the rate of decay depends upon the rate of deposition, though the difference becomes less pronounced as the total time of decay becomes large compared with the time of deposition.

FIG. 3.—Deposition and decay at room temperature.

(a) Deposition of  $1.6 \times 10^{15}$  atoms/cm.<sup>2</sup> ( $3.2 \times 10^{12}$  atoms/cm.<sup>2</sup>/sec.).

(b) Deposition of  $2.0 \times 10^{15}$  atoms/cm.<sup>2</sup> ( $1.6 \times 10^{12}$  atoms/cm.<sup>2</sup>/sec.).

(c) See page 1410.

**(b) Deposition at 125° K.**

At this low temperature, curves of the type of Fig. 4 are obtained, illustrations for different quantities being shown. The decay is very much slower at this temperature, though not completely arrested.

**(c) Relation Between Photo-effect and Surface Concentration.**

As the decay of the photo-effect with the strip at 125° K. is slow compared with the

FIG. 4.—Deposition and decay at 125° K.

time of deposition, it is possible to calibrate the photo-current against the surface concentration, as it follows from the above experiments that the migration of caesium into the mass of the oxide can be neglected to a first approximation.

The result of this calibration is plotted in Fig. 5, the upper curve showing the total photo-emission, the lower curve giving the effect

when the light from the mercury arc was filtered through a glass plate, cutting out all components below 3200 Å. Both curves show marked devia-

FIG. 5.—Calibration of photo-effect against surface concentration.

tion from linearity for low concentrations and flattening out for concentrations of some  $10^{12}$  atoms/cm.<sup>2</sup>, i.e. a few atomic layers. The latter is in good

agreement with the observations of Brady\* who finds that for caesium films on silver the maximum photo electric yield is given by the same order of concentration. From the work of Brady and others it is known that the variation of photo-sensitivity with wave-length depends upon the thickness of the film. The similarity in shape of the curves of Fig. 5 at the high concentrations suggests however that at these thicknesses the sensitivity/wavelength relation has settled down to a standard form. For low concentrations the variation of wave-length sensitivity with thickness must be operative; to this effect we must attribute the relatively flat initial slopes. At any rate we cannot make from these curves any deductions as to the adsorption process with which this work is primarily concerned. Evidence of the spectral distribution does not, of course, show the characteristics of the photo-emission of caesium in bulk, but indicates that we are dealing with an adsorbed layer. In this connection we mention that, while in early rough experiments with iron oxide as base, less than 10 per cent. of the emission was due to light of a wave-length greater than 3200 Å., in the present case up to 60 per cent. is due to this region.

#### (d) Influence of Adsorbed Layers of Gas.

It is *a priori* very unlikely that a decay (over a period of many hours) of photo-electric emission from a strip kept in thermal equilibrium with the rest of the tube (*i.e.*, at room temperature) could be produced by formation of surface layers of gas; such layers should deposit in a few minutes or even seconds, corresponding to the pressures of  $10^{-7}$  —  $10^{-8}$  mm. Hg after the strip has come to equilibrium. Experiments showed that the photo-electric emission was very sensitive to changes in pressure, being lower for higher pressures. Minute traces of gas had a remarkable effect if the strip was at a low temperature (*i.e.*, not at thermal equilibrium with the rest of the apparatus). With the filament at 125° K. such traces would extinguish a high photo-electric effect almost instantaneously or inhibit its appearance during deposition. Indeed in the calibration described under (c) consistency was only obtained by heating the strip to a high temperature while the copper seals were immersed in liquid oxygen, so, as to collect all residual traces on the cold copper leads before cooling the strip itself.

No such difficulties were encountered at higher temperatures; this is consistent with the fact that on warming up the cold strip after deposition had ceased, the photo-emission did not drop immediately but rose sharply at first. The cause of this initial rise due to removal of gas is the reverse of what happens when gas is put on. Clearly, therefore, the phenomenon of decay cannot be attributed to a formation of gas layers and we shall therefore discuss it in terms of migration into the mass of the oxide.

#### (e) Migration into the Mass of the Oxide.

On this view a certain distribution of caesium will be built up in the oxide during the period of deposition, depending on the intensity of the beam and the temperature of the strip. Curve (a) of Fig. 3 shows a steeper decay than curve (b); the rate of deposition was greater in that case, so that larger concentration gradients were built up. Fig. 6 (a) shows on a larger scale an early portion of the upper curve of Fig. 5, and Fig. 6 (b) shows a deposition curve over the same region of surface concentration, but with the strip at 290° K. In spite of the higher beam intensity in deposition (b), these curves show clearly that a greater total amount of caesium is necessary to produce the same surface concentration at the higher temperature. Fig. 7 shows a similar result for the temperatures 291° K. and 397° K. Very different amounts of caesium may, then, be

accommodated in the oxide, although their surface concentration is the same.

As another illustration,  $1.9 \times 10^{18}$  atoms/cm.<sup>2</sup> were deposited at 397° K. and, immediately the beam was cut off the strip was allowed to cool to 290° K. and the decay followed. Curve (c) of Fig. 3 which shows the result may be compared with the decay of (b), Fig. 3. The rate of decay is determined partly by the surface concentration and partly by the rate of supply to the surface of atoms from within the body of the oxide. During the deposition at high temperature a greater concentration in depth is set up by the relatively high migration, so that the decay curves (b) and (c) of Fig. 3 are quite different although they were observed at the same temperature and start from nearly the same surface concentration. The film deposited at high temperature, curve (c), decays more slowly, because of the greater store of atoms beneath the surface. These curves provide further evidence against the possibility that adsorbed gas causes decay, since the gas conditions are the same in the two cases.

FIG. 6.

Curves of deposition.

FIG. 7.

#### (f) Measurements of the Activation Energy Associated with the Migration Process.

Picturing the process of migration as one of simple diffusion with a diffusion coefficient  $D$  characteristic of the substances involved and of the temperature, but independent of concentration (*i.e.* assuming that interaction between caesium atoms can be neglected), we have the classical equation

$$\frac{1}{D} \frac{\partial c}{\partial t} = \frac{\partial^2 c}{\partial x^2}$$

where  $c(x, t)$  denotes the concentration of caesium in any plane parallel to the surface, at a distance  $x$  from it and at the time  $t$ .

According to Bosworth<sup>1</sup> the activation energy is given by

$$E = \frac{d \log_{10} \left( \frac{D}{\sqrt{T}} \right)}{d \left( \frac{10,000}{T} \right)} \quad 1.99 \text{ volts}$$

where  $T$  is the absolute temperature. Its determination requires a knowledge of the *ratio* of the diffusion coefficients for different temperatures.

The method finally chosen to determine such ratios of diffusion coefficients is independent of the calibration "photo-effect against surface concentration" of section (c) and of the finite thickness of the oxide. The ratios are determined from the deposition curves (constant beam intensity) making quantitative use of the fact that for a given temperature of the strip the total amount of caesium producing a given surface concentration varies with the beam intensity. Consider two temperatures  $T_1$  and  $T_2$  at which the diffusion coefficient has the values  $D_1$  and  $D_2$ . The boundary conditions for deposition are:—

(1) Oxide, completely free of caesium at the time  $t = 0$  (beginning of deposition)

$$c(x, 0) = 0 \text{ for all values of } x.$$

(2) At the actual surface  $x = 0$ , the concentration depends on the time  $t$  as determined by the deposition curve:

$$c(0, t) = \text{given function of } t.$$

Condition (2) can be replaced by another, of which the deposition curve is a consequence, *i.e.*, constant beam intensity  $n$ , at which the total amount deposited up to the time  $t$  is proportional to  $t$ :

$$\int_0^d c(x, t) dx = nt \quad . \quad . \quad . \quad (2a)$$

where  $d$  denotes the thickness of the oxide. Taking (1) and (2a) as boundary conditions, (2) is now part of the solution of the differential equation.

This equation, including boundary conditions for the deposition at the temperatures  $T_1$  and  $T_2$  and the beam intensities  $n_1$ , and  $n_2$ , now reads:

$$\begin{array}{ll} (1) & (2) \\ \frac{1}{D_1} \frac{\partial c_1}{\partial t} = \frac{\partial^2 c_1}{\partial x^2} & \frac{1}{D_2} \frac{\partial c_2}{\partial t} = \frac{\partial^2 c_2}{\partial x^2} \\ c_1(x, 0) = 0 & c_2(x, 0) = 0 \\ \int_0^d c_1(x, t) dx = n_1 t & \int_0^d c_2(x, t) dx = n_2 t. \end{array}$$

Now each solution of (1) can be transformed into a solution of (2) by simple reduction of the time scale, owing to the linearity of equation and boundary condition with respect to  $t$ . Writing  $\alpha\tau = t$  in (2), we obtain

$$\begin{array}{l} \frac{1}{\alpha D_2} \frac{\partial c_2}{\partial \tau} = \frac{\partial^2 c_2}{\partial x^2} \\ c_2(x, 0) = 0 \\ \int_0^d c_2(x, \alpha\tau) dx = \alpha n_2 \cdot \tau \end{array}$$

and  $c_2$  is identical with a solution of (1) if

$$\alpha = \frac{D_1}{D_2} = \frac{n_1}{n_2}$$

and  $\tau$  is replaced by  $t$ . Taking therefore the deposition curves as representations of solutions of the sets (1) and (2) we determine the ratio of the diffusion coefficients  $D_1/D_2$  by determining two relative beam intensities  $n_1$  and  $n_2$  for which the respective deposition curves, taken at the temperatures  $T_1$  and  $T_2$ , coincide when plotted against  $n_1 \cdot t$  and  $n_2 \cdot t$ , *i.e.*, the total amounts deposited on the strip. Examples of deposition curves, plotted against total amount deposited have been discussed in section (e). We now see that in order to find the activation energy from such curves we have to plot "families" of them for different temperatures, varying the beam intensity as family parameter. The ratios can then be computed by interpolation.

In actual practice the range of temperature over which the method is practicable is limited. At low temperatures ( $< 250^\circ \text{K.}$ ) the rate of migration is so slow that a variation of the beam intensity within practicable limits does not produce deposition curves sufficiently distinguishable from each other to allow quantitative conclusions; at high temperatures

FIG. 8.

- (a) (b) (c) Family of deposition curves at  $325^\circ \text{K.}$  for various beam intensities.  
(d) Deposition curve at  $342^\circ \text{K.}$

the migration is so fast that very large amounts of caesium are absorbed by the oxide before a reasonable photocurrent is obtained.

Fig. 8 shows three members of the family for the strip temperature  $325^\circ \text{K.}$  The dotted curve represents a member of the family belonging to the temperature  $342^\circ \text{K.}$  According to the above theory the latter

curve should coincide with one curve of the family belonging to the lower temperature. This however is not the case, and evidently the non-similarity is due to the interaction of caesium atoms during the diffusion process which expresses itself macroscopically in a dependence on the diffusion coefficient on the concentration. It must be remembered that the above treatment neglects this "secondary" effect. The interpolation does not therefore lead to a constant value of the activation energy

TABLE.

Activation Energy in Volts.		Surface Concentration, $10^{14} \text{ atoms/cm.}^2$
$334^\circ \text{K.}$	$308^\circ \text{K.}$	
0.39	0.33	2.4
0.42	0.36	3.3
0.47	0.40	4.2
0.51	0.41	4.8
0.57	0.53	5.3
0.61	—	5.6

for a given temperature; the activation energy appears to rise with the surface concentration (see table). This rise, however, has no significance except that it indicates a breakdown of the above theory for higher values of surface concentration. The surface concentrations are derived from the calibration of section (c).

For a temperature of 250° K. values of the order of 0.2 volts were obtained.

We have so far assumed that the simple diffusion equation governs the process of migration into the oxide. This assumption at best is a very crude approximation, for although undoubtedly caesium leaves the surface and enters the body of the oxide, the oxide may not be homogeneous throughout its depth, the diffusion coefficient may depend upon the concentration of caesium in the oxide, as already pointed out, and in the case of experiments conducted at different temperatures the physical structure of the oxide may suffer reversible changes (*e.g.*, opening or closing of cracks between crystalline aggregates). All these circumstances would cause deviations from the simple theory.

The applicability of the diffusion equation might be tested by depositing instantaneously a certain amount of caesium on the surface of the oxide and following the value of the surface concentration  $c$  with time. From the simple diffusion equation,  $c$  should then be proportional to  $1/\sqrt{Dt}$ . This straightforward experiment could not be done, but attempts were made to measure the diffusion coefficient by a method employed by Bosworth.<sup>1</sup> Caesium was deposited on the oxide at a temperature considerably below the temperature at which  $D$  was to be measured. The strip was then rapidly heated to the required temperature after the deposition had been stopped. This should provide a close approximation to the ideal boundary conditions postulated above.

However the curves of photo-electric effect so obtained did not show the form to be expected on this simple hypothesis. All showed a much quicker change in the rate of decay (a steep initial fall followed by a very slow final fall) than the theory predicted. No further test of the applicability of the equation was here available, for it was not found possible to determine the diffusion coefficient for migration *along* the strip in the manner employed by Bosworth. Although up to  $2 \times 10^{16}$  atoms/cm<sup>2</sup> were deposited on the strip, complete saturation with caesium was never attained; even if the decay of photoelectric emission had become very slow at one temperature, it could still always be speeded up by raising the temperature of the strip. One would not, therefore, expect to observe side-ways spreading of the patch, for Bosworth found in his case that saturation in depth had first to be attained before migration along the strip could be detected. We may recall here that Bosworth found the simple theory of diffusion broke down when he was investigating migration along the length of the strip; edgewise spreading of the photo-electrically active patch did indeed occur, but superimposed upon this was a photo-electric emission uniform along the strip. This observation cannot be explained on the simple theory or indeed any obvious modifications of it:

### § 9. Discussion.

A picture of the process we assume as the underlying cause of the phenomena described here is given by Lennard-Jones.<sup>5</sup> He describes the migration of a substance into another crystalline substance as a diffusion along intercrystalline cleavages, perpendicular to the surface. On such a picture, the migration from the surface into the mass of the crystalline substance will depend on the relation between the size and number of the cleavages and the size of the migrating atoms.

On comparing the results obtained in this paper with those of Bosworth<sup>1</sup> one finds a good agreement between the order of magnitude of the activation energies, so that the general nature of the adsorptive forces is the same for the semi-conducting oxide surface as it is for the metallic tungsten. One also finds a somewhat close qualitative

<sup>5</sup> Lennard-Jones, *Trans. Faraday Soc.*, 1932, **28**, 333.

resemblance between his results for sodium on tungsten and the results presented here. This purely accidental agreement is obviously due to two factors: (1) The tungsten strip used in his experiments has a thickness of  $2 \times 10^{-3}$  cm., while the oxide surface used here is at least 10 times thinner, thus presenting ten times less underlying substance. (2) Probably still more important is the fact that the sodium atom is much smaller than the caesium atom. From the picture presented by Lennard-Jones, and also from a comparison of the experiments of Bosworth on sodium and potassium it follows clearly that the migration of caesium into the metal would be much slower than the migration of sodium. At the same time the migration over the surface would become more appreciable because the caesium atom would have to travel over the surface for a considerable distance before finding an empty gap down which it could slip.\*

Bosworth found that the larger potassium atoms were absorbed to a much smaller degree by metallic tungsten than the smaller sodium atoms. If one extrapolates from these to ascertain how caesium would be absorbed by tungsten of a thickness equal to that of the oxide used here, one would find that only about  $10^{14}$  atoms/cm.<sup>2</sup> (a fraction of a monomolecular layer) would actually be able to diffuse inwards, to fill intercrystalline cleavages. We thus come to the conclusion that the oxide has a far more spongy nature than the metal and an adsorption capacity at least a hundred times higher.

In a recent paper (*Physic. Rev.*, 1936, **49**, 670) Brady and Jacobsmeyer have investigated the photoelectric properties of sodium films on aluminium. They find that the photoelectric emission decays over a short period of time after deposition for films of sodium up to a thickness of 80 atoms and suggest that this decay is due to a re-arrangement of the film which breaks up into globules whereby the effective area is decreased. From the fact that in our case the total amount of caesium deposited can be re-evaporated as positive ions and that there is no evaporation of neutral atoms of caesium even at temperatures at which the vapour pressure of caesium is very high, we conclude that such a formation of globules cannot take place in the experiments described here. It is quite possible that in the case of sodium on aluminium too the photo-electric decay is due to a process of migration into the mass of the metal although the decay does not follow the law predicted by the simple theory of diffusion.

I am greatly indebted to Dr. E. T. S. Appleyard for suggesting the problem and for his constant supervision, to Dr. C. F. Powell and Dr. H. Fröhlich for helpful discussions, and to Professor A. M. Tyndall for placing the facilities of the Laboratory at my disposal. I also wish to thank the International Student Service for a grant.

### Summary.

The adsorption of thin films of caesium on a surface of tungstic oxide is studied by a photoelectric method for the temperature range  $125^{\circ}$  K. to  $400^{\circ}$  K. The phenomena occurring are described qualitatively by the assumption that the caesium atoms migrate into the mass of the oxide. Values for the activation energy connected with this migration are derived.

*H.H. Wills Physical Laboratory,  
University of Bristol.*

\* This migration of caesium over the surface of a tungsten filament has actually been investigated by Taylor and Langmuir (*Physic. Rev.*, 1932, **40**, 463) by a thermionic method. The implications of their results are discussed by Bosworth.<sup>1</sup>

# THE SWELLING PRESSURE OF ISINGLASS IN WATER AND AQUEOUS SOLUTIONS.

BY H. FREUNDLICH AND P. S. GORDON.

*Received 15th June, 1936.*

1. Investigation of the swelling pressure has so far only been carried out for rubber in a number of organic liquids.<sup>1</sup> A disc of rubber, exposed to a measured air pressure, was separated from the liquid by a porous medium; the liquid was imbibed by the rubber, and the ensuing change in its volume was measured under a number of different pressures. Similar experiments with aqueous solutions have not so far been so successful.<sup>2</sup> The swelling pressure of gelatin could only be determined in this way near the isoelectric point, for in solutions of acids, alkalis, and salts the gelatin was so strongly peptised that it passed through the pores of the membrane before a well-defined equilibrium could be reached. The process of swelling, it should be pointed out, requires a fairly long time—several hours—to reach completion.

Isinglass, though very similar to gelatin,<sup>3</sup> has a much smaller tendency to be peptised. Thus while 0.5 gm. of gelatin was completely peptised in 0.1 N  $\text{NH}_4\text{CNS}$  in four hours, a similar quantity of isinglass took at least 10 times as long. This is probably due to isinglass having a very distinct structure. Under the microscope one observes a network of long, curling, fibres. The structure is also seen in a complete dried swimming bladder, for if this hard material is broken the fractured ends have the appearance of asbestos. From it, fibres a few cms. in length may easily be separated. The lack of structure in gelatin may be due to the fact that it is prepared by the prolonged boiling of animal tissue, whereas isinglass is simply dried collagen. When isinglass is brought into solution by heating, and afterwards dried, obvious signs of structure disappear. But as the tendency to be peptised remained smaller than that for gelatin, it seemed hopeful to measure the swelling pressure in water and aqueous solutions by the method just mentioned.

2. The apparatus used (Fig. 1) was very similar to that of Posnjak. The glass portion was made of pyrex glass, the wide tube having a height of 7 cm., a bore of 1.25 cm., while the walls were 1.2 mm. thick. The capillary tube had a length of 70 cm., and a bore of 1.5 mm. The upper metal portion of the apparatus, together with the nut, was of mild steel, but the remaining parts, none of which was used in Posnjak's device, were of "Anka brand" stainless steel. The washers were of vulcanised rubber 1 mm. thick. The porous pots were of dried white china clay. As they had not been fired the material was still quite soft, so that they could readily be shortened to the size desired, namely 1 in.  $\times$  1 in. The

<sup>1</sup> Freundlich and Posnjak, *Kolloidchem. Beih.*, 1912, 3, 517.

<sup>2</sup> Freundlich and Posnjak<sup>1</sup>; v. Terzaghi, *Handb. physik. u. techn. Mechanik*, 1931, IV, 2, 555. The swelling pressure of discs of a sea-alga, *Laminaria*, in water was measured by Reinke (*Hanstein's Botan. Abhandl.*, 1879, 4, 1).

<sup>3</sup> The similarity is also shown by the fact that isinglass has practically the same gold number as gelatin; it was 0.0055 mgs., while we found the value 0.01 with the same gold sol and a fairly pure sample of gelatin.

inner surface of each pot was polished with glass paper until smooth, and particular care was taken to have the bottom of the pots, both inside and out, smooth and flat. The space between the porous pot and the glass tube was filled with a cement of yellow litharge and glycerine diluted with water in the proportion of 1 vol. glycerine to 1 vol. water. The cement had initially the consistency of a thin paste, but it set in 24 hours to a hard, porous mass which adhered well to the glass and to the porous pot.

The end of the glass capillary remote from the swelling cell had a copper tube attached with De Khotinsky's cement, and this tube was soldered to a similar tube leading from the air pressure regulating apparatus. The soldered joint could be made or broken in a very short time. Compressed air was stored in a cylinder fitted with a reducing valve. It was led into the apparatus through a needle valve as required, the pressure being released by a similar valve. The pressure was read on a "Standard Test Gauge," made by the Budenberg Gauge Co. A small air reservoir served to minimise the fall in pressure due to any leakage, which proved to be undetectably small over a period of 48 hours.

FIG. 1.—Swelling pressure apparatus.

The accuracy of the pressure gauge, and the uniformity of the capillary tube, was tested before use, and it was found that no corrections need be applied. Two small corrections had, however, to be made to the readings to allow for (a) the elastic expansion of the apparatus under increasing pressure, and (b) the change in volume of the mercury filling the apparatus, which, it should be stated, was filled in this manner: a weighed disc of isinglass (ca. 100 mgms.) was forced into the cell until it was in contact with the porous pot, mercury was poured in until it began to overflow and, having removed any air bubbles clinging to the inner surface of the tube with an iron wire, the nut was screwed on firmly. During this process the mercury was prevented from running down the capillary by a small air pressure, the final position

of the mercury in the tube being about 20 cm. from the swelling cell. The correction (a) was determined experimentally each time the apparatus was set up, while (b) was estimated by considering the apparatus to function as a thermometer. The measurements were made in a cellar room in which the temperature did not vary more than  $\pm 1^\circ \text{C.}$  during the course of an experiment. The correction was  $0.25 \text{ cm./}^\circ \text{C.}$

The chief precaution in setting up the apparatus was to observe that no air was left above the mercury, for the elastic expansion of this masked any effect due to the swelling, and also it easily leaked from the cell, with a consequent permanent movement of the mercury in the capillary. Naturally, care had to be taken that no mercury leaked out. Before any readings were taken the pressure in the apparatus was left at 600 gms./sq. cm. for some hours. If the mercury in the capillary moved no readings were taken.

3. The swelling behaviour of isinglass gels was obviously reversible, for the volume was the same whether it was reached from a higher or a lower pressure. The only factor impairing reversibility was a certain

degree of peptisation. This latter was tested by precipitating with tannin the isinglass which had passed into the external liquid. The amount of isinglass could be estimated reasonably accurately from the degree of turbidity produced. In many cases, e.g. in solutions of NaF and NaCl the amount which passed through the membrane was very small. In other cases, e.g.,  $\text{Na}_2\text{SO}_4$  and especially  $\text{NH}_4\text{CNS}$ , the peptisation was much stronger. As long as the amount peptised did not exceed about 10 per cent. a correction could be applied. But in solutions of acids, alkalis, and some salts, the peptisation became so strong that the method did not give trustworthy results.

Let  $\Pi$  denote the swelling pressure, its value being the pressure read on the gauge plus a small amount (60 gms./sq. cm.) due to the head of mercury between the level of the capillary and the level of the isinglass. It is not correct to include the atmospheric pressure in this quantity  $\Pi$ , as the atmosphere bears equally on the surface of the external liquid.

Let  $\gamma$  be the concentration of the gel, i.e., the amount of isinglass in 1000 c.c. of isinglass + liquid.

Then it was shown that the equation  $\Pi = \Pi_0 \gamma^k$  also holds for isinglass,  $\Pi_0$  and  $k$  being constants as with Posnjak.<sup>1</sup> The straight lines in the diagrams (cf. Figs. 3-7) show how far this equation agrees with experiment.

It must be emphasised that in swelling pressure we are dealing with a reversible quantity, similar to gas or osmotic pressure. This type of experiment must be sharply distinguished from those in

FIG. 2.—Variation of swelling with  $p_H$ .

which the maximum of swelling is determined simply by allowing a gel to swell in a liquid without doing any external work. In the latter case we are dealing with an irreversible process similar to the solution of a substance in a liquid.

The reversibility of the swelling is shown by the fact that all the points lie, for any particular case, on the same straight line irrespective of the pressure from which they were reached. (Cf. the line for LiCl in Fig. 3.) Further, the regular linear shape of these curves is not disturbed by the small changes of temperature ( $\pm 1^\circ$ ) which occurred in the period necessary for measuring one of these curves. This shows that small changes of temperature do not cause marked changes in the degree of swelling.<sup>4</sup>

Before entering on details concerning the equation, another point ought to be discussed. As a protein, isinglass is strongly sensitive to changes in the  $p_H$  of the solution. The influence of  $p_H$  on the swelling of isinglass was investigated in  $M/20$  acetate buffers, of  $p_H$  between 2.8 and 9.5. In Fig. 2 is shown the variation of the swelling under a constant pressure of 3060 gm./sq. cm. It will be seen that the gel concentration

<sup>4</sup> This agrees on the whole with the results of Jordan Lloyd and Pleass, *Biochem. J.*, 1927, 21, 1356. Cf. also Northrop and Kunitz, *J. Gen. Physiol.*, 1927, 10, 167.

changes between 410 and 630, with a maximum of gel concentration at a  $p_H$  of about 6.5; i.e., there is a minimum of swelling close to the isoelectric point, which was found<sup>5</sup> to be at about 5.9. This agrees with the results of Chiari,<sup>6</sup> and Lloyd and Pleass,<sup>4</sup> that there is a minimum of swelling at the isoelectric point. The small deviation from the value of 5.9 is most probably due to the relatively large buffer concentration; it is well known that ions other than  $H^+$  and  $OH^-$  may displace the isoelectric point to a certain degree.<sup>7</sup>

The minimum of swelling at the isoelectric point is not at variance with the maximum of the sedimentation volume of isinglass coated quartz particles at the same  $p_H$ , for in the latter case it is the  $\zeta$  potential of the particles which is decisive.<sup>8</sup> The amount of isinglass adsorbed is probably so small that the change in volume of the surface layer due to swelling is negligible. The adsorption of isinglass on quartz has not so far been determined, but the extreme similarity between this substance and gelatin renders it practically certain that the adsorption with isinglass is the same as the known adsorption with gelatin.<sup>9</sup>

When comparing the influence of different electrolytes upon swelling pressure we did not fail to take into account the possibility of a  $p_H$  change in the solution. Such a change did, in fact, occur. The solution became more alkaline than pure water in solutions of LiCl, NaCl, KCl,  $CaCl_2$ ,  $SrCl_2$ , NaI,  $NaNO_3$ ,  $KIO_3$ ,  $Na_2SO_4$ , and it became more acid in solutions of  $BeCl_2$ ,  $La(NO_3)_3$ , NaF; in  $TiNO_3$  solutions the displacement of the  $p_H$  was very small, being a little to the alkaline side. The values found are given in Table I.; the changes in  $p_H$ , which were measured in every

$NH_4CNS^*$ . . .	5000-6000	(6.2)	8	Very strong	13

\*  $NH_4CNS$  could not be investigated thoroughly owing to the very strong peptisation observed in its solutions. The equation could not be verified. Hence this value was extrapolated assuming that  $k$  was the same as for NaI and choosing the gel concentration where peptisation had been least.

<sup>2</sup> Freundlich and Gordon, *Trans. Faraday Soc.*, 1935, 31, 915. The high value of the isoelectric point of isinglass compared with the value generally accepted for gelatin (4.7) agrees well with the results of Dubitzkaja and Sokoloff (*Kolloid. Z.*, 1935, 72, 205). They found that the isoelectric point of pure collagen lies above 5 and decreases when the latter is treated with alkalis.

<sup>6</sup> Chiari, *Biochem. Z.*, 1911, 33, 167.

<sup>7</sup> For instance Michaelis and Rona, *Biochem. Z.*, 1919, 94, 225; Lloyd and Pleass<sup>4</sup>; Ljalikow, Protass and Fajerman, *C.R. Acad. Sc. U.R.S.S.*, 1935, 1, 615; *Chem. Zentr.*, 1936, 1, 3470.

<sup>8</sup> Freundlich and Gordon.<sup>5</sup>

<sup>9</sup> Lindau and Rhodius, *Z. physik. Chem., A*, 1935, 172, 321.

case with a universal indicator, are not of accidental occurrence, for, if the solution was removed and replaced with fresh solution, this rapidly took up the same altered  $p_H$  value. If the gel was removed from the apparatus at the conclusion of the experiment and heated until it formed a solution, the  $p_H$  of the liquid so formed was found, by the use of the same indicator, to be identical with that of the external solution.

Returning to the discussion of the equation, it was found that the exponent  $k$  for isinglass in pure water was slightly larger than the value of about 3 found in the case of gelatin.<sup>1</sup> But gelatin swells more than isinglass: the swelling pressure for a gel concentration  $\gamma = 500$  is about 2000 for isinglass and 3000 for gelatin.

Figs. 3-5 and Table I. show that in salt solutions  $k$  varies rather strongly—and independently of the change of  $p_H$ —according to the nature of the electrolytes. The values found for the chlorides of alkali metals are much smaller than for those of the polyvalent metals, and for salts with other anions.

There are substances (e.g.,  $\text{NH}_4\text{CNS}$ ,  $\text{NaI}$  etc.) in solutions of which swelling is markedly stronger than in pure water. In solutions of most substances swelling is less than in water, the diminution being particularly strong in solutions of  $\text{Na}_2\text{SO}_4$ ,  $\text{LiCl}$ , and  $\text{BeCl}_2$ . Such a behaviour has been known since Hofmeister,<sup>10</sup> Pauli,<sup>11</sup> Wo. Ostwald,<sup>12</sup> Katz,<sup>13</sup> and others, published their results on swelling, but in all these cases objections ap-

peared justifiable on the grounds that the methods of investigation were not well defined: some were not isothermal or reversible; others were not free from the influence of swelling velocity or peptisation. Our experiments suffered from none of these defects, though the method of comparison was arbitrary in so far as the electrolyte concentration was concerned, and also in comparing the effects at  $\gamma = 500$ . One could compare the values of  $\Pi_0$ , but since this is the swelling pressure at a concentration 1, it would mean an extreme extrapolation. A small change in a  $k$ -value caused by any experimental error would thus cause a large error in  $\Pi_0$ . It therefore seemed better to compare values of a swelling pressure for a concentration closer to the region with which the

curves were measured at the additional concentrations of  $0.1\text{N}$ ,  $0.5\text{N}$ , and  $1.0\text{N}$ , these readings being supplemented by measurements of the swelling in salt solutions of differing concentrations, but under a fixed swelling pressure. (The  $p_H$  values in the three additional cases were respectively 8, 9.5, and 9.5, while the temperatures were 17.5, 19, and 17.)

While in each of the cases just mentioned the linearity of the  $\log \Pi / \log \gamma$  curves remained un-

changed, and while the peptisation was small, Fig. 6 shows that the influence of salt concentration was not at all simple. In a range of small concentrations (between  $0.1$  and  $0.5\text{N}$ ) swelling shows an initial decrease and then an increase with rising concentration; at higher concentrations it decreases again. Comparison is made difficult, however, by the fact that  $k$  rises strongly with increasing concentration, the values being 3.8, 4.1, 5.6, and 14 for  $0.1$ ,  $0.2$ ,  $0.5$ , and  $1.0\text{N}$  solutions. The swelling at a fixed pressure of 1060 gms./sq. cm. is compared in Table II.

Some preliminary results with calcium chloride also gave a rise of  $k$  with increasing concentration, but the change in swelling was much smaller. It may be remarked that the measurements of other authors,<sup>14</sup> using quite different methods, have shown that the influence of concentration on the swelling is very complicated.

The solutions of two non-electrolytes were also investigated, namely urea and cane sugar. The urea had a concentration of  $0.833$  moles/litre, and the cane sugar  $0.146$ . Both experiments were at  $15^\circ$ , and in both the  $p_H$  was 7. The  $k$ -values were respectively 6.0 and 9.5. In each case

the equation held, and the results agree with older results in that cane sugar caused a marked decrease in swelling.<sup>15</sup> The solution of urea was not very different in effect from pure water (cf. Fig. 7).

Now, as isinglass is very similar to gelatin it is probable that it is not simple in its chemical constitution. Northrop and Kunitz<sup>16</sup> fractionated gelatin by a suitable treatment of the aqueous solution with alcohol and at a low temperature (0° C.). They obtained two fractions, the more soluble one having a higher osmotic pressure and a smaller viscosity than the other. An attempt was made to repeat their method with isinglass, and a certain separation was achieved. The two fractions obtained both appeared to be proteins, though their properties were remarkably different. The soluble fraction, which was present in large excess, had a slight yellow colour. It had a strong swelling power, and dissolved with great ease in warm water. These solutions did not gel on cooling unless the concentration was distinctly larger than with the original material. The insoluble fraction had quite the opposite properties. It was a grey powder, only soluble in water with difficulty. Further, when the solution was cooled the result was not a gel, for the material separated in flocks. It was not, therefore, possible to measure the swelling pressure of the latter fraction by our method. This could only be done with the more soluble fraction. It was compared with the original isinglass in a 0.2*N* sodium chloride<sup>17</sup> solution.

Table III. shows that the more soluble fraction has a higher swelling pressure than the original isinglass. This appears to agree with the results of Northrop and Kunitz that their soluble fraction of gelatin had a higher osmotic pressure.

#### 4. These experiments show that the relation between swelling pressure

and gel concentration given by the equation holds very generally for aqueous solutions. The equation is only empirical, but the range it covers is fairly broad.<sup>18</sup> The impression which might be gained from the experiments mentioned above<sup>1</sup> that the exponent  $k$  varies very little with the nature of the gel and of the liquid—being about 3—was not confirmed;  $k$  may attain very much higher values—up to 8 or more—in aqueous solutions of high concentration of the dissolved substance and with electrolytes with polyvalent ions.

FIG. 7.

Curve for water shown dotted.

As mentioned already our experiments concerning reversible and isothermal swelling phenomena agree fully with previous measurements done with less well-defined methods on gels of gelatin, starch, etc.<sup>10-13</sup>

The results show that salts may change the swelling pressure strongly independent of change of  $p_H$ . One example may prove this assertion: in a 0.2*N* sodium sulphate solution the  $p_H$  of the swollen gel was 8.5. If swelling pressure depended only on the  $p_H$ , according to Fig. 2, one would have expected an increased swelling: in water (of a  $p_H = 6.0$ ) a swelling pressure of 3060 gm. sq. cm. would correspond to a gel concentration of 612, whereas for a  $p_H = 8.5$  one would have, corresponding to an increased swelling, the smaller value of 520. But in the sodium sulphate solution the gel concentration actually corresponding to this swelling pressure was higher, 865; swelling had decreased.

This behaviour agrees with an assumption, now very generally favoured,<sup>19</sup> that swelling is a complex phenomenon and cannot be explained on the ground of only one physico-chemical process. Most likely, changes in swelling due to a change of  $p_H$  have to be distinguished from the changes caused by neutral electrolytes and non-electrolytes. The former phenomenon is frequently explained as a Donnan effect.<sup>20</sup> Others<sup>21</sup> prefer to correlate this influence of  $p_H$  upon swelling with a change in the electrical charge of the gel micellae. It seems difficult if not impossible, to correlate the influence of neutral salts with a Donnan effect, because, as was discussed in the example of sodium sulphate, it does not depend on the change of  $p_H$  which is observed.

The influence of the ions is obviously related to their position in the lyotropic or Hofmeister's series<sup>22</sup>  $\text{Li} < \text{Na} < \text{K}$  and  $\text{SO}_4 < \text{F} < \text{Cl} < \text{NO}_3 < \text{I} < \text{CNS}$ . All facts known so far seem to prove that the order of the ions in these series has to do with the order of their hydration.<sup>23</sup> The ions might influence the swelling by changing the amount of water bound to the gel micelles. This action would depend strongly upon the way in which the ions are distributed in the gel; whether they are bound to the micellae or are in the intermicellar liquid.<sup>24</sup> Swelling would be favoured if markedly hydrated ions are adsorbed strongly by the micellae. According to Katz<sup>25</sup> this is why the thiocyanate ion and other ions and molecules of similar structure, favour swelling so definitely: they are hydropolar substances containing a hydrophobic and a hydrophilic group; the hydrophobic group is advantageous as to adsorption in an aqueous medium, the hydrophilic one is the cause of the hydration. On the other hand, if the ion is negatively adsorbed (*i.e.*, if it prefers to remain in the aqueous medium) swelling may decrease, so long as the strongly hydrated ion can rob the micelles of their water molecules. It is actually known that sulphates,

for instance  $K_2SO_4$ , are adsorbed negatively by gelatin;<sup>26</sup> the same holds for sugars with tanned gelatin, ovalbumen, etc., as adsorbants.<sup>27</sup>

There does not appear to be a correlation between the influence of salts on swelling and their peptising action; sodium thiocyanate and iodide both cause an increase of swelling, but while the former favours peptisation, the latter does not do so.<sup>28</sup>

The conception of bound water is, perhaps, still open to objection. But it is a fact that a certain amount of water in concentrated gelatin gels does not turn to ice even at very low temperatures<sup>29</sup> and that about the same amount is unable to hydrate blue  $CoCl_2$  in a gelatin gel.<sup>30</sup> This seems to show indirectly that in concentrated gels, at least, a part of the water is bound very strongly to the micelles and may compete with the water bound to the ions or molecules of dissolved substance.

### Summary.

1. The swelling pressure of isinglass in water and aqueous solutions of a number of electrolytes and a few non-electrolytes (urea and cane sugar) has been determined at room temperature with a device similar to that of Posnjak. This could be done because isinglass is peptised in these solutions much less than gelatin.

2. Swelling is reversible. The equation correlating swelling pressure  $\Pi$  and concentration of the gel  $\gamma$  (in grams of isinglass per 1000 c.c. isinglass + liquid) is

$$\Pi = \Pi_0 \gamma^k$$

$\Pi_0$  and  $k$  being constants.

3. The swelling of isinglass is on the whole similar to that of gelatin, both as to the absolute amount and as to the value of  $k$  (4.7 for isinglass and 3 for gelatin). For isinglass in many other aqueous solutions, especially at higher concentrations and with polyvalent ions,  $k$  may attain much higher values (8 or more).

4. The influence of different ions was compared at a salt concentration of 0.2N. In the presence of some electrolytes ( $NaI$ ,  $NH_4CNS$ ) swelling is stronger than in water. In that of others (specially  $Na_2SO_4$ ,  $BeCl_2$ , and  $La(NO_3)_3$ ) it is markedly less. These changes do not depend on the small changes of  $p_H$  caused by the electrolytes. As to the intensity of their effects the ions may be arranged in Hofmeister's series  $Li < Na < K$  and  $SO_4 < F < Cl < NO_3 < I < CNS$ .

5. The influence of the electrolyte concentration  $c$  was investigated thoroughly only in sodium chloride solutions. It was not at all simple;  $k$  increases with increasing  $c$ , especially at higher salt concentrations.

6. The influence of  $p_H$  on the swelling of isinglass was measured in acetate buffer solutions in a range between 2.8 and 9.5 at a constant swelling pressure of 1060 gms./sq. cm. There was a minimum of swelling at about 6.5, close to the isoelectric point of isinglass (about 6). A minimum of swelling near the isoelectric point has also been found in other cases.

<sup>26</sup> Dumanski, *Z. physik. Chem.*, 1907, **60**, 559. Cf. also the well-known experiment with pig's bladder and a very concentrated sodium chloride solution performed by Ludwig (*Pogg. Ann.*, 1849, **78**, 320).

<sup>27</sup> R. O. Herzog, *Z. physiol. Chem.*, 1908, **57**, 315. Herzog and Adler, *Kolloid. Z.*, 1908, **2**, II. Supplem., p. iii. Berczeller, *Biochem. Z.*, 1918, **90**, 290.

<sup>28</sup> Hence we do not agree with Holwerda, *Biochem. Z.*, 1935, **282**, 340, that increased swelling always leads to increased peptisation.

<sup>29</sup> Moran, *Proc. Roy. Soc., A*, 1926, **112**, 30.

<sup>30</sup> Hatschek, *Trans. Faraday Soc.*, 1936, **32**, 787.

7. The swelling of isinglass decreases markedly in the presence of sugar; urea has a weaker influence in the same sense.

8. The gold number of isinglass was 0.0055, fairly close to the value found for gelatin with the same gold sol (0.01).

## NOTE ON THE RELATIONSHIP BETWEEN $\zeta$ POTENTIAL AND STABILITY IN EMULSIONS.

BY CONMAR ROBINSON.

*Received 16th June, 1936.*

Harkins and his co-workers have carried out work which indicates that the stability of an emulsion increases in general as the emulsifying film changes from an expanded to a condensed film.<sup>1,2</sup> Thus, if an oil emulsion is formed with sodium oleate, Fischer and Harkins were able to show (by determining the size distribution of the droplets) that at first the droplets increase in size, but eventually reach a stable size distribution. Further, when this stable size distribution is reached they showed, by determining the amount of sodium oleate adsorbed on the droplets, that the interfacial concentration of sodium oleate corresponds to a condensed monomolecular film.

The following theoretical point which gives one reason for the importance of the condensed monomolecular film does not seem to have been previously discussed.

If we consider an oil in water emulsion stabilised by a paraffin chain electrolyte such as sodium oleate, the ions will be symmetrically distributed on the surface of the droplets, with the paraffin tails embedded in the oil and the lyophilic heads turned towards the water. The concentration of ions on the surface, even though it is not enough to give a condensed monomolecular layer, may be enough to give a charge density and resulting  $\zeta$  potential which would be high enough in the case of a lyophobic sol to prevent the particles from coming into contact with one another. With the liquid particles of an emulsion, however, we suggest there will be a very important difference. As the droplets approach one another, the long chain ions, the negatively charged heads of which repel one another, will be redistributed, the ions slipping round the surface of the droplets until there are comparatively few ions on the opposing faces. Consequently, the  $\zeta$  potential at that part of the surface of each droplet nearest the approaching droplet will be lowered so much that coalescing will take place.

If, however, there is a condensed monomolecular film on the surface, the ions cannot slip round the droplets and hence we have the optimum conditions for stability. (It would seem probable that a surface concentration very near to that which would give a condensed monomolecular film would be equally efficient provided the ions on the interface were

<sup>1</sup> Harkins and Beeman, *J.A.C.S.*, 1929, **51**, 1674.

<sup>2</sup> Fischer and Harkins, *J. Physic. Chem.*, 1932, **36**, 98.

sufficiently crowded together to correspond to the steep portions of the force area/curve, *i.e.* where a considerable increase in lateral pressure is necessary to bring about any further decrease in the area occupied by an ion.) Thus while the stability of a lyophobic sol is dependent on the  $\zeta$  potential of the particles exceeding a certain critical potential  $X$ , which will be given by a comparatively low surface concentration  $A$  (see Fig. 1), the stability of an emulsion will not be governed by the  $\zeta$  potential of the isolated particle (curve I), but by the  $\zeta$  potential on opposing faces of close drops (curve II) which will only reach  $X$  at some higher surface concentration  $B$ . Only where the surface concentration reaches the value for a condensed monomolecular film will the  $\zeta$  potential of the isolated particle in the emulsion be the same as that at the opposing faces of near drops.

Hence, when considering the stability of oil emulsions stabilised by paraffin chain ions, it is most important to determine the

FIG. 1.

concentration of solution which will give a surface concentration which is nearly that corresponding to a condensed monomolecular film. This surface concentration will probably be attained with a solution concentration of paraffin chain electrolyte which gives the maximum lowering of interfacial tension. On the other hand, cataphoretic measurements will be of little interest, as these can only give the  $\zeta$  potential of the isolated drops.

## ON THE MICROTHERMOCONDUCTIVITY METHOD FOR THE ESTIMATION OF PARA-HYDROGEN AND DEUTERIUM.

BY D. D. ELEY AND JAMES L. TUCK.

*Received 18th June, 1936.*

The microthermoconductivity apparatus for the estimation of *para*-hydrogen, invented by A. Farkas<sup>1</sup> and extended by A. and L. Farkas<sup>2</sup> to the estimation of deuterium, has been successfully used by a number

<sup>1</sup> A. Farkas, *Z. physik. Chem., B*, 1933, **22**, 344.

<sup>2</sup> A. Farkas and L. Farkas, *Proc. Roy. Soc., A*, 1934, **144**, 467.

of workers,<sup>3</sup> some of whom mention the practical difficulties involved in the application of this method. A modified version of the apparatus has been published by Wirtz,<sup>4</sup> who also gives a discussion of the technical points concerned. In connection with an investigation of the exchange reaction between hydrogen and water, an apparatus similar in some points to that of Wirtz, has been independently developed in these laboratories. In view of its importance for this work, and the practical difficulties experienced in its construction, it has been considered desirable to publish a short account.

### The Apparatus.

The essential points are shown in Fig. 1. The cell G, of soft glass, contains a loop of platinum strip wire<sup>5</sup> (0.05 mm.  $\times$  0.005 mm.) 17 cm. long, held taut by a quartz-fibre and silver-soldered at each end to the

FIG. 1.

sealing-in wire. The leads to the cell are taken through an evacuated stem<sup>6</sup> (20 cm. long) and the whole gauge is deeply immersed in a bath of liquid air, the level of which is kept constant (a thermocouple junction, not indicated, is used to "detect" the level, and from time to time liquid air is blown in from a siphon).  $U_1$  protects the cell from Hg vapour, tap-grease, and so on. M has a volume of 150 c.c. and serves both as a cut-off, eliminating taps in the vital part of the system, and as a pressure-adjusting device.\* An asbestos box, indicated by dotted lines, protects it from

<sup>4</sup> K. Wirtz, *Z. physik. Chem.*, B, 1936, **32**, 335.

<sup>5</sup> Knauer and Stern, *Z. Physik*, 1929, **53**, 766.

<sup>6</sup> See also Taylor and Diamond.<sup>3</sup>

\* This eliminates the use of a needle-valve. We found needle-valves to have the following disadvantages: (a) they were not really vacuum tight, (b) imperfections in grinding and fluctuations in pumping speed gave an imperfect adjustment of pressure, (c) they gave a separation of the hydrogen isotopes (see <sup>4</sup>).

draughts; the gauge is very sensitive to pressure alterations consequent on room temperature fluctuations and it is essential that the pressure in the cell should be constant over one minute, which is the time required for a resistance reading. The cell Ni contains the heated nickel wire which is used to bring  $p\text{H}_2 \rightleftharpoons n\text{H}_2$  reaction to equilibrium; liquid air traps protect it from tap-grease, etc. Calibration gases are admitted through taps  $T_3$  and  $T_4$ , the unknown mixture at  $x$ .

### The Measurements.

For the theory of the apparatus, the reader is referred to the papers of Farkas,<sup>1, 2</sup> whose symbols <sup>3</sup> we use in the following.

Hydrogen is introduced via  $T_2$  and its pressure (as indicated on the galvanometer, with a given current  $i_1$ , and the Wheatstone bridge set at  $R_1$ ) is lowered by pumping via a "lock," until it is lower than required. The mercury in M is then run up, and by use of the vent, I, the pressure in the gauge can be very accurately adjusted.

The measurements concerned are analyses of  $p\text{H}_2$  and HD in mixtures of the two (deuterium  $< 4$  per cent.). Because of drifts in resistance value, it is found necessary to measure  $n\text{H}_2$  with every experimental determination, and to measure a calibration mixture of  $p\text{H}_2$  and HD every day. Measurements are made in the order  $n\text{H}_2 = \Delta$  ohms;  $p\text{H}_2 + \text{HD} = \Delta + (a + b)$ ; the gas is now brought to equilibrium by circulation over the red-hot nickel wire, and introduced into the cell,  $n\text{H}_2 + \text{HD} = \Delta + a$ ;  $n\text{H}_2 = \Delta$ . Then  $[p\text{H}_2] \sim b$ ,  $[\text{HD}] \sim a$ . 3.2 per cent. D gas gives  $a = 0.45 \Omega$  on our apparatus, the value varying from day to day by 0.01  $\Omega$ , with maximum fluctuations of  $\pm 0.03 \Omega$ .  $\Delta$  has been observed to decrease 0.3  $\Omega$  in a day, but after some days' working it becomes fairly constant. The resistance values  $a$  and  $b$  are reproducible to  $\pm 0.01 \Omega$  or  $\pm 0.1$  per cent. D. The diurnal decrease of  $\Delta$  may be due to alteration in accommodation coefficient, or solution of hydrogen in the wire with subsequent diminution of the temperature coefficient of resistance.<sup>7</sup>

A number of points in connection with the apparatus have been observed:—

1. Increase of temperature of the liquid air round the cell decreases the resistance shifts, particularly that due to HD.
2. Each time the gauge is first adjusted an "adsorption effect" occurs. On making the necessary current adjustments and resistance measurements,  $i_1(R_1)$ ,  $i_2(R_2)$ , then back to  $i_1(R_3)$ , it is found that  $R_3 < R_1$ , in fact,  $R_1 - R_3$  is of the order of 0.05  $\Omega$ , indicating a slight increase of pressure in the gauge. The pressure is readjusted and measurements made until  $R_1 = R_3$  within 0.005  $\Omega$ .
3. With the "untreated" wire,  $p\text{H}_2$  conversion has been observed in the cell, giving a very quick drift of resistance value down to the deuterium value ( $\Delta + a$ ), where it remains constant. The conversion does not go at  $T_1$ , but only at the higher  $T_2'$  and so goes through the "high-temperature mechanism." It was stopped by poisoning the wire with hydrogen in the treatment outlined below. (The poisoning effect of hydrogen on this type of reaction is well known.<sup>8, 9</sup>)
4. Finally, a treatment was developed for putting the cell into working condition after accidental admission of air, etc. The objects are (a) to clean the wire, (b) to give an adsorbed layer of hydrogen stable at the working pressure (0.05 mm. Hg) and the upper temperature  $T_1'$  (about 0° C.), (c) to poison the wire to the  $p\text{H}_2$  conversion.

The cell is pumped for about six hours at 150° C., "overheating" the wire (resistance at 0° C. equals 100  $\Omega$ ) with 10 mA. Liquid air is round U<sub>1</sub>. The wire is then glowed red for thirty seconds, and then both wire and cell are reduced slowly in temperature over five hours. 10<sup>-1</sup> mm. of H<sub>2</sub> are left in the cell overnight; the liquid air bath is then placed round the cell and the H<sub>2</sub> pumped away. A number of actual "measurements" serve to bring about the fine adjustment of the sorbed quantity of hydrogen, upon which the stable working of the apparatus appears to depend.

In general, five minutes are spent over a measurement (i.e. about twenty minutes for a complete analysis of *p*H<sub>2</sub> and HD, including the time required for pumping). The minimum quantity of gas that can be handled with our apparatus, which has a large dead space, is about 0.05 c.c. at N.T.P. It should be possible to reduce this to 0.01 c.c., by using a circulating pump with a smaller dead space and cutting down the volume of the cut-off and the tubing.

The authors wish to express their best thanks to Professor M. Polanyi for invaluable help and advice.

## THE PLATINUM ELECTRODE AS A CATALYST FOR THE ACTIVATION OF HYDROGEN.

BY M. CALVIN.

*Received 24th June, 1936.*

It has long been known that metals catalyse the establishment of the equilibrium between H<sub>2</sub> molecules and H<sup>+</sup> ions in solution, but the precise mechanism has not yet been completely elucidated. The essential series of reactions usually considered is

Upon the assumption that (2) or its reverse is the rate determining step in the deposition of hydrogen, Erdey-Gruz and Volmer<sup>1</sup> and Frumkin<sup>2</sup> have given a derivation of the empirically found relation

$$\epsilon = a + b \log i \quad (3)$$

between current *i* and cathodic overvoltage  $\epsilon$  (high) at a hydrogen electrode. Horiuti and Polanyi<sup>3</sup> have recently extended this conception and given a more detailed account of the mechanism of the reaction with some plausible reason for the value of the constant *b*. Upon the basis of an analysis of the current-voltage relation for small polarisations, which does not conform to equation (3) Hammett<sup>4</sup> came to the conclusion that the speeds of processes (1) and (2) were both of the same order of magnitude, and that small variations in the condition of the electrode

<sup>1</sup> Erdey-Gruz and Volmer, *Z. physik. Chem.*, A, 1930, 180, 203.

<sup>2</sup> Frumkin, *Z. physik. Chem.*, A, 1933, 164, 121.

<sup>3</sup> Horiuti and Polanyi, *Acta Physicochimica U.S.S.R.*, 1935, 2, 520.

(polarisation, surface, etc.) might make one or the other predominant. The same conclusion has been arrived at by Knorr and Schwartz.<sup>5</sup>

In all of these theories there are two opposing currents, that of oxidation and that of reduction, which are balanced at the potential of the reversible hydrogen electrode. Should this be the case it is reasonable to assume, with Horiuti and Polanyi, that the exchange reaction between deuterium and water

which has been shown to be catalysed by platinum black<sup>6</sup> should go through such a series of steps and should provide a measure of the two currents flowing at zero overvoltage. If (2) is the limiting process the rate of exchange should be affected by the polarisation of the electrode at which it is measured. The following contains a report upon some exploratory experiments done to measure this effect and also the effect of polarisation upon the para-ortho-hydrogen conversion.

### Experimental.

The apparatus used is shown diagrammatically in Fig. 1. It consisted essentially of a

reaction vessel V, containing the catalyst electrode E, a polarising anode A, a hydrogen reference electrode H, and a tube T leading to the saturated calomel electrode C. This was connected to a circulating pump and the high vacuum pumps so that the system could be well evacuated and a given sample of  $\text{H}_2 - \text{D}_2$  gas circulated through the cell for long periods of time. M is a manometer, J a water jacket for condensing water vapour from

FIG. 1.

the outward flowing gas, and at S a sample bulb could be attached for withdrawing a quantity of the hydrogen to be analysed for its deuterium content. This analysis was made by means of a quartz-fibre gas density micro-balance, constructed after the design of Whytlaw-Gray, Patterson and Cawood,<sup>7</sup> and could easily be carried out to within 0.1 per cent.

<sup>5</sup> Knorr and Schwartz, *Z. physik. Chem., A*, 1930, **176**, 161; *Z. Electrochem.*, 1934, **40**, 38.

<sup>7</sup> Whytlaw-Gray, Patterson and Cawood, *Proc. Roy. Soc.*, 1931-32, **134**, 7. The author is indebted to Dr. Cawood for personal advice concerning the construction of the balance.

The polarising current was drawn from a 110 volt dry battery through a variable high resistance, so that the polarisation in the cell did not alter the current density, once set. The potential measurements were made on a Cambridge potentiometer capable of measuring 0.01 millivolt.

Since the pressure in the cell was always less than atmospheric it was necessary to make the connection to the calomel cell through a sintered glass plate P, backed by a fairly hard agar gel G made in saturated KCl. This was found to give satisfactory electrical connection and would hold the atmosphere against 17 mm. (vapour pressure of water) with only an extremely slow leak of about 5 c.c. of solution in a week. This could be completely eliminated by reducing the air pressure in the calomel cell to something only a few mm. higher than that existing in the reaction vessel V. The whole reaction vessel V, could be immersed in a dewar flask containing ice water. The total volume of reaction vessel and circulating system was 800 c.c.

All the metal electrodes were made of platinum, the anode A and the hydrogen electrode H being 0.5 mm. wire. The electrode E is shown in section. It is a square tube 5 cm. long and 2 cm., on a side, containing nine baffle plates arranged as shown, made of plate 0.05 mm. thick. The total area both inside and out is 150 cm.<sup>2</sup> Thus the gas in passing up through the baffles must make intimate contact with the metal, and since between each stroke of the circulating pump the electrode fills with solution which must be pushed out again at the next stroke, the solution is also well stirred by the circulating gas.

All three electrodes were platinised in the usual manner from a 3 per cent. solution of platinum chloride containing 0.025 per cent. of lead acetate. The electrode E was never made anodic in the course of this process, H being used to platinise A. During the course of the experiments the electrode remained jet black in colour except after it had been made anodic for a considerable period after which it became grey.

The hydrogen used was about 99 per cent. D, made by electrolysis the corresponding heavy water in a KOH solution. It was purified by passage through a palladium thimble.

**Procedure.** After the electrodes had been platinised and cleaned of traces of chloride by cathodic discharge of hydrogen and washing in distilled water, the cell was assembled and evacuated until the pressure of residual gas was less than  $10^{-5}$  mm. The solution was then admitted from the reservoir R until it covered the electrode E. This solution contains dissolved air and the pumping is again continued until the residual gas pressure falls to less than  $10^{-4}$  mm. The system is allowed to stand evacuated for 24 hours and any gases which may have come out of solution during that time are again pumped off. A sample of thimble ordinary hydrogen is then admitted through the tap S and circulated through the cell for a few minutes to saturate the solution with hydrogen and then the process of evacuation is repeated. After this deuterium is admitted to the desired pressure, 200-300 mm., circulated for a few minutes and a sample for analysis taken in a liter bulb at S. About 200 c.c. of gas at 300 mm. pressure are required for analysis but this gas is returned to the system with only a small loss, by means of the gas transfer vessel, L, so that after each sample is taken and returned the total pressure of the system has fallen only by 5 to 8 mm. In the case of the  $pH_2$  conversion only very small samples were required since the analysis was made by means of the micro-thermal conductivity method of Farkas, and many samples could be completely removed without appreciably altering the pressure.\*

**Results.** In the first experiments done in water the polarisation of the electrode was not measured because of the low conductivity of the solution and the consequent high ohmic drop in the solution between the standard electrode and the catalysing electrode. The exchange reaction

\* Thanks are due to Mr. D. D. Eley for making these measurements.

velocity was measured as a function of the potential difference maintained between the anode A and the electrode F. The data so obtained at 20° C. and 0° C., are given in Table I. and plotted in Fig. 2, the points for water being represented by circles. In the Table, P is the polarizing potential maintained between A and F and  $p$  is the pressure of the gas in the system. The data is tabulated in the order in which they were obtained showing that the changes there apparent are quite reversible. The variation in the unimolecular velocity constant  $k = 1/t$  in  $C_0/C_t$  to be expected from the variation in pressure appearing here is within the experimental error <sup>9, 10</sup> of  $k$ .

In Table II. are given the results obtained on 0.01 N H<sub>2</sub>SO<sub>4</sub>, the plate having been replatinised between these measurements and the preceding ones.

$\phi_0$  and  $\phi$  are the potentials of the unpolarised and polarised plate respectively against the saturated calomel electrode;  $\Delta\phi$  will then be the over-voltage or polarisation of the

the points are represented by x. The cathodic polarisation was not carried any further because of the commencement of gas evolution. The temperature variation of  $k$  obtained from measurements at 20° at 0° C., and back again to 20° C., gives an activation energy of 8100 calories for the exchange reaction.

A series of measurements using the electrode H as a reference electrode was also carried out, but it was found that the potential of H was very greatly influenced by the condition of the electrode F, and hence the results, although qualitatively the same as the other experiments cannot be quantitatively compared with them.

A series of experiments to determine the effect of potential upon the rate of  $pH_2$  conversion was run in  $N$   $H_2SO_4$ . Gas containing about 3 per cent. D and about 20 per cent. excess  $pH_2$  over the equilibrium concentration was introduced into the system, and then small samples withdrawn at the desired intervals to be measured for their HD and  $pH_2$  content simultaneously.\* The results, though as yet only qualitative, indicate that the  $pH_2$  conversion is accelerated under those conditions which retard the exchange reaction.

FIG. 3.

In order to establish the relationship between the electrode used here and those used by other workers the change of potential with quantity of electricity passed was determined, in addition to the ordinary current-polarisation measurements. The potential-coulomb curves were taken between the small platinised electrodes A and H in 0.01  $N$   $H_2SO_4$  saturated with hydrogen at 277 mm. pressure. Starting with H in the condition of the reversible hydrogen electrode it was made anodic and a constant current allowed to pass. The change of potential as measured against the saturated calomel electrode is plotted as a function of time and

the result is in agreement with that of Slygin and Frumkin<sup>11</sup> with the depolarising action of the dissolved  $H_2$  taken into account. The curves obtained by plotting  $\log i$  against cathodic polarisation were similar to those obtained by Hammett<sup>4</sup> and by Knorr and Schwartz.<sup>5</sup> A typical result is shown in Fig. 3.

### Discussion.

One fact, immediately evident from these data, is that a comparatively small cathodic polarisation has the effect of greatly reducing the reaction velocity of the exchange reaction and that rather large anodic polarisations up to a certain point have no effect upon this reaction velocity. These data are as yet insufficient to warrant an attempt at a full quantitative interpretation. We will be concerned here with pointing out the restrictions that must be imposed on any theoretical explanation of these results.

Anodic polarisation has no effect upon the velocity constant below about 0.7 volt positive to the reversible hydrogen potential. This result has been recently reported for a Ni electrode by Horiuti and Okamoto.<sup>12</sup> If the plate is kept at some potential higher than this for a time long enough to measure the exchange velocity (10-20 hours) the velocity constant is reduced, irreversibly, to practically zero if the plate is sufficiently positive, and even prolonged cathodic discharge of hydrogen will not reactivate the surface. It is interesting to note that this critical potential of about 0.7 volt corresponds to a point of inflection in the potential-coulomb curves described by Slygin and Frumkin,<sup>11</sup> and also observed on this particular electrode. It is reasonable to believe that at this point the attack of the metal atoms of the electrode by the discharged anions commences and thus the surface is irreversibly changed as far as its catalytic activity is concerned.<sup>13</sup>

Before any predictions concerning the effect of potential on the exchange velocity can be made, it should be noted that the passage of a current to or from the electrode must increase the rate of exchange by the corresponding amount. Since no oxygen is evolved (it would appear in the gas and manifest itself in the gas density measurements immediately), it must be reduced at the anode by dissolved hydrogen as fast as it arrives and hence deuterium would disappear from the gas in proportion to the current passed, while exactly the same amount of hydrogen would appear at the cathode, which is already saturated with hydrogen. The relevance of this effect can be estimated from a comparison of the velocity constant on the unpolarised plate with the current passed for polarisation. The velocity constant of the exchange reaction can be expressed as a pair of equal oppositely directed currents and the value of  $k_0$  at 20° C., 0.0062, gives an equilibrium current for the plate used of  $4.7 \times 10^{-3}$  amps., taking 800 c.c. for the volume of the gas at 300 mm. pressure. At 0° C. this would be reduced to  $1.9 \times 10^{-3}$  amps. These are to be compared with the currents of the order of  $10^{-3}$  amps. which are required to maintain cathodic overvoltages around 0.01 volt and currents up to  $5 \times 10^{-3}$  amps. for the anodic polarization, at this same electrode. It is apparent that in acid solutions the exchange due to electrolysis would be an important part of the total exchange both for cathodic and anodic

<sup>11</sup> Slygin and Frumkin, *Acta Physicochimica U.S.S.R.*, 1935, **3**, 791.

<sup>13</sup> Butler and Drever, *Trans. Faraday Soc.*, 1936, **32**, 427; Previous work cited.

polarisation. This excess exchange was not observed even when the current passed corresponded to more than 50 per cent. of the total amount of hydrogen in the system. In the case of pure water as the electrolyte, the electrolysis current was always negligibly small and hence it was possible in this case to get a complete cessation of the exchange reaction as far as could be measured by the means employed.

It is evident that (2), ionization, cannot be rate determining, since in that case the velocity constant should vary with polarisation  $\epsilon$  according to (3),

$$\ln k_{\epsilon} = \ln k_0 + \frac{\alpha \epsilon F}{RT} \quad . \quad . \quad . \quad . \quad (5)$$

neglecting the smaller of the two balanced equilibrium currents the difference between which constitutes the electrolysis current.\* Hence anodic polarisation should increase the rate of the exchange. If anything, the anodic polarisation actually reduces the catalytic exchange.

It may be suggested that the inability of anodic polarisation to accelerate the reaction according to (5) might be due to the limiting processes of solution or diffusion of molecular hydrogen, both of which would be unaffected by polarisation. These possibilities are rejected since the temperature coefficient of the reaction velocity is too large for such limiting processes, and moreover it seems that the para hydrogen conversion can be made to go as much as ten times faster than the exchange reaction by simply applying a small cathodic overvoltage.

The retarding effect of cathodic polarisation eliminates the possibility that (1), atomisation, be rate determining provided the atoms and molecules are in such a condition on the metal surface as to be unaffected by polarisation.

It is important to note that the form of equation (5) remains the same, if the exchange reaction velocity is assumed to be effectively limited by any single process, the activation energy of which is the only quantity effected by polarisation. We therefore turn to considerations in which the effect of two consecutive phases is taken into account.

Upon the basis of work on the current-overvoltage relation it has already been proposed by Hammett<sup>4</sup> that both (1) and (2) are important in limiting the rate of hydrogen deposition. If the activation energies of the two successive processes are about equal and are not affected by polarisation in the same way it may be possible to reconcile our results with such a mechanism. In order that polarisation may have an effect on the activation energy of (1), it is necessary that the structure M—H or M—H<sub>2</sub> be electrically asymmetrical, i.e. polar. From a consideration of the effects of adsorbed gases and vapours upon the thermionic and photoelectric properties of metals it has been quite definitely shown that the surface electric fields of metals distort the adsorbed atoms or molecules with the resultant formation of dipoles.<sup>14, 15</sup> Suhrmann and Csech have reported that adsorbed hydrogen atoms lower the work function of such metals as Pt, Au, Ag, and hence the dipoles should be oriented with their positive ends away from the metal surface.<sup>16</sup> The

\* Actually these currents cannot be neglected in the polarisation ranges under discussion, but the simplified equation is used since this abbreviates the arguments without effecting its result.

<sup>14</sup> J. H. De Boer, *Electron Emission and Adsorption Phenomena*, Cambridge, 1935.

<sup>15</sup> De Boer, and Veenemans, *Physica*, 1935, 2, 915.

<sup>16</sup> Suhrmann and Csech, *Z. physik. Chem., B.*, 1935, 28, 215.

opposite conclusion as to the orientation of the dipoles of adsorbed hydrogen on tungsten has been reported by Roberts<sup>17</sup> upon the basis of experiments indicating a decrease in the heat of adsorption of hydrogen on tungsten with increasing fraction of the surface covered. For metals in contact with hydrogen and acid solutions Bowden<sup>18</sup> has indicated that the dipoles will have their positive ends away from the metal surface while Slygin and Frumkin<sup>11</sup> propose the reverse. Since both Roberts, and Slygin and Frumkin base their conclusions upon observations of the work of removal of the first monatomic layer of hydrogen on the metal surface, while Bowden, and Suhrmann and Csech were certainly working with more completely saturated surfaces it may well be, as De Boer<sup>14</sup> has proposed for adsorbed alkali atoms, that the primarily adsorbed layer of dipoles is oppositely oriented from the successive ones. In any case, whichever way the dipoles may be oriented, a change in the electric field in which they are situated will affect the activation energy of their combination.

Another possibility is that other factors besides the activation energy are affected by polarisation. Upon the assumption that a single reaction dominates in limiting the reaction velocity the general relation for the variation in reaction velocity constant with any parameter (in this case polarisation  $P$ ), as given by Evans and Polanyi,<sup>19</sup> can be introduced. It is given by

$$\frac{\partial \ln k}{\partial P} = \frac{\beta_1 - \beta_r}{RT} \quad (6)$$

where  $\beta_1$  is the derivative of the free energy of the initial state with respect to the parameter  $P$  (polarisation) and  $\beta_r$  is the same quantity for the transition state. Thus in general  $\beta$  is given by

$$\beta = \frac{\partial(H - TS)}{\partial P} \quad (7)$$

where  $H$ ,  $T$ , and  $S$ , have their usual thermodynamic significance. If the entropy term is independent of polarisation equation (5) is obtained if  $H_r - H_1$  is taken as the activation energy of the reaction. But as has already been indicated the structures  $M-H$  and  $M-H_2$  are in all probability polar and hence the entropy of these states will not be independent of polarisation and an effect of polarisation upon terms other than the activation energy must result.

These possibilities are being fully investigated in these laboratories and a comprehensive discussion will be withheld until these results are available.

The author wishes to express his great indebtedness to Professor M. Polanyi for suggesting these experiments, for many discussions and his constant interest in this work, and for the opportunity to work in these laboratories.

### Summary.

1. The exchange reaction  $D_2 + H_2O \rightarrow HD + HDO$  catalysed by a platinized platinum electrode has been investigated in neutral and acid solution.

<sup>17</sup> J. K. Roberts, *Proc. Roy. Soc.*, 1935, **152**, 459.

<sup>19</sup> Evans and Polanyi, *Tr. Far. Soc.*, p. 1333.

<sup>18</sup> Bowden, *Proc. Roy. Soc.*, 1929-30, **126**, 107.

2. It has been found that small cathodic polarisations retard the reaction reversibly, while large anodic polarisations up to about .7 volt do not increase the reaction velocity. At higher anodic polarisation the reaction is irreversibly inhibited.

3. Some theoretical implications of these results are discussed, and it is shown that no unmodified existing theory can account for them.

## ACTIVATION OF HYDROGEN BY PHTHALOCYANINE AND COPPER PHTHALOCYANINE.

### PART I.

BY M. CALVIN, E. G. COCKBAIN AND M. POLANYI.

*Received 25th June, 1936.*

The experiments reported in this paper were undertaken in the hope of throwing some light on the mechanism by which enzymes activate hydrogen. While the activation of hydrogen by metal catalysts and the similar action of metal oxides can, to some extent, be accounted for by the formation of surface hydrides, it is as yet completely unknown how an organic compound, such as the enzyme must be, can act as a hydrogenase.

The observations described below, that crystals of phthalocyanine and of copper phthalocyanine can activate molecular hydrogen, might indicate a line of approach to this problem. We seem to have here a pure organic body activating hydrogen, and we have reason to hope that the mechanism of this action will not be difficult to elucidate. It is significant that phthalocyanine contains a central ring very similar to that of porphin, which is the structural nucleus of chlorophyll and hæmin, as well as of various enzymes related to hæmin playing a part in biological oxidation. The structure of phthalocyanine as proved by Linstead<sup>1</sup> is

<sup>1</sup> R. P. Linstead, *J.C.S.*, 1934, 1016.

The existence of a long chain of conjugated double bonds in phthalocyanine also suggests an analogy to the numerous biologically active substances containing such chains. The questions arising from such considerations are being considered in a theoretical communication by Mr. M. G. Evans and one of the authors. In this and the following paper we shall describe only our first observations on the action of phthalocyanine and some parallel experiments with copper phthalocyanine.

### Materials.

Our samples of phthalocyanine and of copper phthalocyanine were both obtained by the courtesy of the Imperial Chemical Industries Ltd.; the compounds were prepared and purified by Dr. R. P. Linstead as described by him. We are greatly indebted to both Messrs. The Imperial Chemical Industries Ltd., and Dr. Linstead for their help in making this work possible.

The samples were composed of purple prismatic crystals about 0.5 mm. long and 0.3 mm. thick. The shape of these crystals was similar to those described by Robertson<sup>2</sup> in his X-ray analysis of the phthalocyanines. On distillation in vacuo at 400° C. our samples of phthalocyanine sublimed without leaving a residue. The formation of a trace of a white substance (probably phthalodinitrile) was observed, and occasionally, when the distillation was carried out at higher temperatures, some green non-volatile residue, insoluble in quinoline, was obtained. A microanalysis of 50 mg. of phthalocyanine (combustion with an excess of concentrated sulphuric acid) left no trace, *i.e.*, less than 0.001 mg. of ash.

When small amounts of phthalocyanine are sublimed in vacuo the deposit forms a lustreless green mass with no signs of crystalline structure under a magnification of 250-fold. In a number of experiments we have dissolved this deposit and recrystallised it into normal purple crystals. Since it was important to eliminate any traces of metals we carried out the distillation of some samples in quartz vessels and after sealing off the side tube from which the original crystals had been sublimed we dissolved the green phthalocyanine sublimate in quinoline which had been freshly distilled in quartz. The crystals obtained from this solution were washed with ether, also freshly distilled in quartz. Alternatively, benzophenone and alcohol (both distilled in quartz) were used instead of quinoline and ether respectively.

The hydrogen employed was purified by passing through palladium while the oxygen used was ordinary cylinder gas.

### I. Atomic Interchange between Hydrogen and the Phthalocyanines.

When phthalocyanine or copper phthalocyanine is heated with hydrogen containing deuterium, an atomic interchange is observed between the hydrogen and the phthalocyanine. This is shown by the following experiments:

1. 100 mg. of phthalocyanine were heated for 16 hours at 377° C. in 150 c.c. of hydrogen (containing 7.07 per cent. D) at a pressure of 203 mm. At the end of this period the pressure was unchanged. The D-content of the hydrogen had dropped to 6.65 per cent.
2. Another 100 mg. of phthalocyanine were heated for 20 hours at 450° C. in 150 c.c. of hydrogen,  $p = 170$  mm., D-content = 7.07 per cent. At the end of this period the pressure was again unchanged, while the D-content of the hydrogen had dropped to 5.97 per cent. The phthalocyanine distilled to the cool parts of the tube and deposited in purple needles. Some undistilled green residue (see previous section) remained

<sup>2</sup> Robertson, *J.C.S.*, 1935, 615.

in the heated part of the tube. 60 mg. of the purple crystals were combusted and the water formed showed 1.13 per cent. D-content. If the

is certainly not restricted to the hydrogen atoms in the central ring.

3. 100 mg. of copper phthalocyanine were heated for 21½ hours at 404° C. in 150 c.c. of hydrogen containing 7.07 per cent. D at a pressure of 182 mm.

"distribution factor" for D between molecular hydrogen and organic hydrogen (in CH or NH) is assumed to be about unity the result indicates that 19 per cent. of the H-atoms in phthalocyanine participate in the exchange. Since the distribution factor is, in fact, more favourable to the organic hydrogen, it might be that only about 10 per cent. of the hydrogen atoms participate in the reaction, which could correspond to the two H-atoms in the central ring. The question whether H-atoms in this central ring are more (or less) readily exchanged than those attached to the four benzene rings cannot be decided yet. The fact that copper phthalocyanine also shows an interchange with molecular hydrogen proves that interchangeability

The pressure again remained unchanged and the D-content of the hydrogen fell to 6.81 per cent.

4. The same sample of 100 mg. of Cu phthalocyanine was heated for 25 hours at 500° C. in 150 c.c. of hydrogen containing 90 per cent. D, at 116 mm. pressure. The D-content of the hydrogen fell to 62.4 per cent. In the course of this experiment the substance distilled off and deposited in long purple needles on the cool parts of the tube. 60 mg. of the purple crystals were combusted and the water produced contained 12.6 per cent. D. Again, assuming a distribution ratio of unity, about 17 per cent. of the hydrogen atoms of the Cu phthalocyanine have taken part in an exchange reaction.

Further experiments which prove the interchange between the phthalocyanines and molecular hydrogen are to be found in the following section.

FIG. 3.

- I. 100 mg. freshly sublimed phthalocyanine in quartz,  $t = 293^{\circ}\text{C}$ .  
From analysis, partial pressure of oxygen at A = 135 mm.; at B  $\leq 1$  mm.  
Theoretical pressure drop corresponding to a stoichiometric combination of  $\text{H}_2 + \text{O}_2$  is 402 mm.; observed pressure fall is 382 mm.; difference of 20 mm. due to water vapour. (No liquid air trap used.)
- II. 50 mg. of phthalocyanine, sublimed in pyrex.  
Portion LM,  $t = 285^{\circ}\text{C}$ .  
Portion NR,  $t = 345^{\circ}\text{C}$ .  
At L  $p_{\text{O}_2} = 150$  mm.; at S  $p_{\text{O}_2} = 134$  mm.  
Theoretical pressure drop is 48 mm., observed pressure fall is 44 mm. (Liquid air trap used.)

## II. Phthalocyanines Catalysing the Interchange between Hydrogen and Water.

The experiments described below show that the phthalocyanines are also capable of catalysing the atomic interchange between deuterium and water vapour.

A sample of the catalyst was heated in a sealed pyrex tube with 90 per cent.  $\text{D}_2$  and 50–60 mg. of  $\text{H}_2\text{O}$ . After the experiment the density of the water, and in some cases the D-content of the remaining hydrogen as well as that of the phthalocyanine, were determined. The results are presented in the table.

The blank experiments show that while at a temperature exceeding to that any of the catalytic experiments a trace of interchange was present,

Catalyst.	Volume of Gas.	Pressure at 20° C.	Temperature of Reaction C.	Time, Hours.	Final D— of Gas.	D of Water.	D in Catalyst.

no exchange occurred in the range in which the catalytic experiments were performed.

FIG. 4.

Temperature 202° C.; in Quartz.

- I. About 100 mg. freshly sublimed phthalocyanine. (Activity much greater than that of original samples.)
  - II. Sample I. on succeeding day. (Activity much reduced.)
  - III. Sample II. after recrystallisation from benzophenone and washed with alcohol.
  - IV. Another 100 mg. of phthalocyanine recrystallised from quinoline and washed with ether.
- (Operations mentioned for III. and IV. carried out in quartz, as described in text.)
- V. Expt. II. Fig. 1.

Experiments 1, 2, 5, and 7 show that the temperature coefficient of the catalysed reaction is small, corresponding to an activation energy in the vicinity of 6 K. Cals.

It is apparent from a comparison of experiments 3 and 8 with experiments 1 and 2, that the copper phthalocyanine as we have it is less active as a catalyst for the exchange be-

tween deuterium and water, than is free phthalocyanine.

### III. Combustion of Hydrogen in Oxygen Catalysed by Phthalocyanines.

The formation of water from its elements is catalysed by phthalocyanines at temperatures between 250° and 370° C. The experiments were carried out by heating 50-100 mg. of free phthalocyanine or its copper derivative with mixtures of  $H_2$  and  $O_2$  in tubes of pyrex glass and in quartz vessels.

Out of a great number of experiments, a few representative examples are described below. Blank experiments showed that the reaction was very minute below  $370^{\circ}\text{C}$ . in the absence of a catalyst. The reaction never failed to proceed when crystalline phthalocyanine (purple) was used, but the microscopically amorphous green deposit produced by sublimation of phthalocyanine was erratic in its action. To test this deposit formed by sublimation, a vessel was used with a small side tube from which the material was distilled into the body of the vessel. Whatever residue remained was left in the side tube outside the heated zone. When larger quantities (100 mg.) of phthalocyanine are distilled in vacuo, it is possible to obtain a very active crystalline sublimate which easily loses most of its excess activity, however, during its catalytic action on the  $\text{H}_2 + \text{O}_2$  reaction.

In several experiments a side tube immersed in liquid air was used to condense the water vapour formed. Nevertheless, a certain amount of

Fig. 5.

ance to diffusion) fell off.

In order to test whether the  $\text{H}_2$  and  $\text{O}_2$  disappeared in stoichiometric amounts the gas was repeatedly analysed by measuring its density (after passing through a liquid air trap) with a quartz gas density balance.<sup>9</sup> The result showed that the pressure fall was actually due to a stoichiometric combination of  $\text{H}_2$  and  $\text{O}_2$ .

The analysis by gas density measurement is correct only if no gases are formed during the reaction which can pass the liquid air trap. The absence of such gases was demonstrated by passing the analysed gas over heated copper, copper oxide, when complete disappearance of the gas took place.

We found traces of a gas formed during the catalytic reaction which condensed in the liquid-air-cooled side tube and was released at solid  $\text{CO}_2$  temperature. In general, no precautions were taken against contamination of the catalyst by the vapours of tap grease or mercury. Such precautions

<sup>9</sup> Whytlaw-Gray, Patterson, and Cawood, *Proc. Roy. Soc., A*, 1931, 134, 8.

are actually unnecessary since some experiments, in which such vapours were cut off by a liquid air trap, differed in no way from the others.

Fig. 1 shows a few blank experiments made in the pyrex tubes and quartz tubes actually used for the catalytic experiments. These curves are indicated by a dotted line in the later diagrams which represent various runs using phthalocyanine and copper phthalocyanine. The specific conditions of each experiment are indicated in the legend.

Fig. 2 shows the reaction on several different samples of phthalocyanine at a number of temperatures. In Fig. 3 are longer runs, one of which was carried to completion, *i.e.*, all the oxygen present consumed. The partial pressures of the oxygen, as obtained by analysis are indicated

account of the possibility of oxidation and  $\text{CuO}$ ,  $\text{Cu}$ , catalysis.<sup>4</sup>

#### IV. Experiments on Solution of Phthalocyanines and on Other Organic Compounds.

An attempt was made to find the exchange reaction between deuterium and phthalocyanine in solution. As solvent we used benzophenone at

<sup>4</sup> No such objection can be raised against the reactions on copper phthalocyanine described in the preceding section, in which no oxygen was present. Dr. Linstead has stated in a private communication that no free metal should be present in either the phthalocyanine or the  $\text{Cu}$ -phthalocyanine with which he supplied us.

300° C., quinoline at 270° and 310° C. (in a sealed tube) and cold concentrated  $\text{H}_2\text{SO}_4$ , in all cases with negative results. It seems that solvation blocks the catalytic centres of the phthalocyanine molecules.

These negative experiments demonstrate that quinoline and benzophenone certainly are incapable of reacting with molecular hydrogen. An experiment in which anthracene was heated for 20 hours at 300° with  $\text{D}_2$ , also showed no exchange.

### Summary.

1. Crystals of phthalocyanine and of copper phthalocyanine have the capacity to activate molecular hydrogen. (a) They show atomic interchange with molecular hydrogen. (b) They catalyse the atomic interchange between molecular hydrogen and water vapour. (c) They catalyse the formation of water from hydrogen and oxygen.

2. The activation energy of (b) is very small, in the vicinity of 6 K cal. The activation energy of (c) is larger, being about 18 K cal.

## ACTIVATION OF HYDROGEN BY PHTHALOCYANINE AND COPPER PHTHALOCYANINE. PART II.

BY M. CALVIN, D. D. ELEY AND M. POLANYI

*Received 25th June, 1936.*

The conclusion reached in the previous paper that molecular hydrogen is activated by phthalocyanine compounds receives further support from the observation described below showing that *para*-hydrogen is converted into normal hydrogen by crystals of phthalocyanine and copper phthalocyanine. The rate of conversion was found to have a positive temperature coefficient, hence it is not a paramagnetic effect ("low temperature mechanism"), but must be due to a disruption of the hydrogen molecules ("high temperature mechanism").<sup>1</sup>

### Experiments and Discussion.

Three samples, I., II., III., of phthalocyanine were used. I. was the original material as obtained from Dr. Linstead. II. and III. are the same samples that were used in experiments IV., Fig. 4, and III., Fig. 4, respectively of the previous paper, *i.e.* substances distilled and recrystallised with special precaution. The *para*-conversion was carried out after the  $\text{H}_2 + \text{O}_2$  experiments in the same vessels. Preliminary to the introduction of *para*-hydrogen the catalyst was baked out for an hour in vacuo at 300° C. The *para*-hydrogen, which was about 10 per cent. excess over the equilibrium concentration, was analysed by the micro method of Farkas<sup>2</sup> in the modified apparatus of Eley and Tuck.<sup>3</sup> In the table the rates of conversion are expressed in terms of first order constants  $k$ . Evidence that the reaction is first order is given below.

From experiments 5 to 8 an activation energy of 5700 calories was derived (Fig. 1). Experiments 10 to 13, represented in Fig. 2, show the first order rate. Comparison of experiments 10-13 with 14, and of 8 with 9 show that a 20-fold change of pressure does not effect the rate constant.

\* Average of 3 analyses. These were taken by extracting small quantities of gas by means of a lock, at various times.

† Average of 4 analyses made at various times.

These observations conform with the assumption that the conversion is due to adsorption on a set of centres of uniform energy, the heat of desorption being — 5600 calories or less.

A comparison of the results on samples I., II., and III. shows that distillation and recrystallisation in quartz vessels, a process which might be expected to remove or at least greatly to reduce any traces of free metal originally present in the material, has no effect on the catalytic activity. We consider, therefore, that this activity is due to the pure organic substance.

The observed activation energy of 5700 calories is of the same order as the activation energies observed for the *para*-hydrogen conversion on metal surfaces. The fact that our conversion rates are slower than those obtained on metals is only partly due to the smallness of the active surface which is of the order of 10 cm.<sup>2</sup> (see previous paper). A comparison of the total number of molecules striking the surface having an energy greater or equal to 5700 calories with the actual number converted leads to a "steric factor" of 10<sup>-5</sup>. The reaction thus appears to have a very small entropy factor arising, no doubt, mainly from a very precise configuration of the transition state in co-ordinate space.

A few experiments carried out on copper phthalocyanine show that its action is very similar to that of free phthalocyanine. The two samples, IV., V., of copper phthalocyanine were the untreated original crystalline material as obtained from Dr. Linstead. The samples in quartz vessels were baked out at  $330^{\circ}\text{C}$ . in vacuo for about an hour. Both the amount of conversion expressed in the absolute value of the constants and the activation energy of about 5000 calories obtained from experiments 16, 17, 18, are quite similar to the corresponding data of phthalocyanine.

A certain amount of "low temperature" conversion is to be expected since copper phthalocyanine is paramagnetic,<sup>4</sup> but the positive temperature coefficient indicates that at the temperatures under consideration the conversion proceeds predominantly through a disruption of the H--H bond as is the case with free phthalocyanine.

The activation energy involved in the activation of hydrogen by the phthalocyanine is so small that the processes arising from it should easily be observable at ordinary temperatures if the phthalocyanine could be spread out so as to present a large surface area. Experiments are in progress to realize this condition. A monolayer of 100 mg.

FIG. 1.

FIG. 2.

<sup>4</sup> Klemm and Klemm, *Z. praktische Chemie*, 1935, 143, 82.

of phthalocyanine having an area of  $10^8$  cm.<sup>2</sup> would convert per second, at 40° C., 80 c.c. of *para*-hydrogen at the prevailing pressure. From a similar calculation based on the (quite provisional) figure of 17,500 calories for the activation energy of the  $H_2 + O_2$  reaction catalysed by phthalocyanine we obtain an oxygen consumption of 25 c.c. for 100 mg. of catalyst.

These figures show that minute quantities of phthalocyanine spread out in a monolayer can activate hydrogen at body temperature at a rate far exceeding the rate of respiration; the actual burning of hydrogen, however, would be slower than the rate at which oxygen is consumed by the human body.

Although the positive temperature coefficient of the *para*-hydrogen conversion indicates that the reaction goes through a stage involving the disruption (weakening) of the H—H bond, this does not necessarily imply that the  $H_2 + D_2 = 2HD$  reaction will go at the same rate, a correspondence which has been observed by Fajans on nickel surfaces.<sup>5</sup> Such will be the case only if the mobility of the resulting H atoms on the phthalocyanine is so great that the probability of molecular desorption of any hydrogen atom with its original partner is not greater than the probability of desorption with another adsorbed hydrogen atom. In the case of the phthalocyanine it would seem that the probability of desorption of the original pair is great since the chemisorption of the hydrogen molecules may take place in the central squares formed by four nitrogen atoms of each phthalocyanine molecule. Such activating centres would be widely separated from one another, and there would be little chance of atomic interchange between pairs absorbed on different centres. Future experiments on the  $H_2 + D_2$  reaction will elucidate this point.

It is to be expected that compounds related to the phthalocyanines also exhibit their capacity to activate hydrogen. Similar tests are being carried out on chlorophyll, haemin, and related compounds.

### Summary.

1. Crystals of phthalocyanine and copper phthalocyanine catalyse the conversion of *para*-hydrogen into normal hydrogen.
2. The activation energy of the conversion on free phthalocyanine is 5700 calories, while that on copper phthalocyanine is about 5000 calories; the temperature independent factor is small and the first order constant is independent of pressure.
3. The positive temperature coefficient of the reaction shows that it involves a disruption of the H—H bond by chemisorption.
4. A few milligrams of a substance acting like phthalocyanine spread out into a monolayer could account for the rate of metabolism in the human body.

# POLAROGRAPHIC INVESTIGATIONS OF ANHYDROUS ACETIC ACID SOLUTIONS.

BY D. MACGILLAVRY.

*Received 30th June, 1936.*

Over potentials can be conveniently studied experimentally, using the polarograph as designed by Heyrovsky,<sup>1</sup> especially as a single experiment gives a complete curve of the relationship between potential and current for the cell under investigation.

Though the specific influences of the cations present in aqueous solutions on the conduction of the current are well understood <sup>2</sup> the theoretical interpretation of many other details still remains doubtful.<sup>3</sup> The difficulties arising in the theoretical interpretation result from the fact that we are dealing with systems not in thermodynamical equilibrium, so that in addition to the properties determining such equilibria, we have to take into account the velocities of all the possible mechanisms governing the conduction of the current.

Up to the present only aqueous solutions have been investigated with the polarograph. Much work has been done on the waves caused by cations and on the maxima caused by oxygen and other "surface active" substances. It is not known whether these polarographic characteristics are dependent only upon the solutes regardless of the solvent, or if marked changes will occur when working with the same solutes in other solvents. The importance of this question is apparent.

This paper describes some preliminary experiments with solutions in anhydrous acetic acid. The polarograms obtained reveal features which are quite distinct from the well-known phenomena shown by aqueous solutions.

## Experimental.

Anhydrous acetic acid was prepared by adding borontriacetate in slight excess to 99.8 per cent. acetic acid and fractionating the mixture. This method has been described by Eichelberger.<sup>4</sup> The anhydrous acetates were prepared by crystallisation from mixtures of acetic acid and acetic anhydride followed by recrystallisation from anhydrous acetic acid.<sup>5</sup>

All experiments were carried out with the dropping mercury cathode and a mercury anode. Most of the solutions were used in the ordinary small cells with flat bottoms giving a large anode area. In order to work with small volumes of solution a special cell was constructed (see Fig. 1). The use of an anode with a small area was possible, since with dilute solutions the currents were very small.

<sup>4</sup> W. C. Eichelberger, *J. Am. Chem. Soc.*, 1933, 55, 3633.

<sup>5</sup> I. M. Kolthoff and A. Willman, *ibid.*, 1934, 56, 1007.

The Nejedly galvanometer had a sensitivity of  $9.29 \times 10^{-8}$  amp. for 1 mm. deflection at a distance of 1 meter. The sensitivity was reduced when necessary with a Nejedly reductor box. In the actual set up the scale was 30 cm. from the galvanometer, so that 1 mm. along the current axis was equivalent to  $3.1 \times 10^{-8}$  amp. The series of parallel potential lines were 100 mm. long and 10.5 mm. apart in the original polarograms.

Since the simplest polarograms in water are obtained with the salts of heavy cations and stable anions, these experiments deal mainly with solutions of heavy cations in anhydrous acetic acid. It is of interest first to compare pure acetic acid and distilled water. The cations of both solvents are hydrogen ions. Hence, one might expect a gradual transition from the well-known polarograms of acid solutions to those of the pure solvents. This is not the case; at least no hydrogen waves or any changes due to deposition of hydrogen could be observed.

Very dilute solutions of HCl all give polarograms consisting of an almost horizontal part at lower voltages, a sudden break, and a logarithmically rising part at higher voltages. At still higher voltages the steeply rising part flattens off to the saturation current. With one particular cell a polarogram was first taken with the sensitivity of the galvanometer reduced to 1/100. Then, after addition of KCl another polarogram was

taken. The conductivity had increased so much, that the sensitivity of the galvanometer could be reduced to 1/2000. A hydrogen wave could no longer be traced, the amount of hydrogen ions being too small to be detected with the lower sensitivity. The polarogram showed only the usual potassium wave.

Next, a polarogram of a cell filled with distilled water was taken with sensitivity 1/10. The curve obtained is a nearly straight line, only slightly curved over the whole length, being convex to the voltage axis. The polarogram shows no break nor waves throughout the whole voltage range up to 3.8 volts. No special surface phenomenon is revealed. It is interesting to note that the oscillations caused by the dropping mercury cathode increase proportionally with the total current intensity.

FIG. 1.

Anhydrous acetic acid is a very poor conductor. Therefore the cathode was placed at very small distance from the large anode surface, the distance being kept just large enough to prevent the mercury droplets from touching the anode. With this cell, even using the highest sensitivity, only a very slight deflection of the galvanometer, increasing with the voltage, was observed.

It is evident from these observations, that the acetic acid, like water, contributes very little to the conductivity of the solutions at all voltages and that all waves and other specific phenomena are caused by the dissolved substances. This does not mean that the solvent cannot have a great influence on the general appearance of polarograms, as we shall have occasion to note.

### Acetic Acid Solutions of one Electrolyte.

All the acetic acid solutions investigated behave quite differently from aqueous solutions, in that it was never necessary to free them from dissolved oxygen, so that the ordinary precautions to exclude oxygen from the solutions were quite superfluous. The appearance of an oxygen maximum in some of the polarograms was probably due to the presence of oxygen together with traces of water; such maxima could be made to vanish by passing nitrogen through the cell.

A second interesting peculiarity is that all polarograms obtained with dilute solutions are almost perfectly straight lines (Fig. 2). The oscillations

caused by the cathode always increase proportionally with the total current. This was observed with the dilute solutions of  $\text{HCl}$ ,  $\text{LiCl}$ ,  $\text{NaCH}_3\text{CO}_2$  and with the saturated solutions of  $\text{Cu}(\text{CH}_3\text{CO}_2)_2$  and  $\text{Cd}(\text{CH}_3\text{CO}_2)_2$ . This behaviour suggests that the slowest process determining the rate of electric conduction takes place in the interior of the solutions, probably partly because of the high resistance. However, the entire absence of waves characteristic for the cations is very remarkable. The polarograms of these dilute solutions are similar to those obtained with acetic acid and water, in this respect that no waves are found, although the dilute solutions in acetic acid have a higher conductivity than that of the pure solvent. The sensitivity of the galvanometer was reduced, for instance, to  $1/4$  with the saturated solution of  $\text{Cu}(\text{CH}_3\text{CO}_2)_2$ .

FIG. 2.

With more concentrated solutions of  $\text{NaCH}_3\text{CO}_2$  the following observations were made (Fig. 3). At voltages up to 2 volts the current density increased slowly. At about 2 volts the polarograms show a sudden bend, apparently caused by the  $\text{Na}^+$  ions. At still higher voltages the curve is almost perfectly straight, the slope being greater than at voltages below 2 volts. This section of the polarogram is different from that obtained in aqueous solution, since the change in current is proportional to

the increase of voltage, whereas in aqueous solution the relationship is a logarithmic one. Furthermore, even at 7.6 volts no indication of a saturation current could be detected.

FIG. 3.

Thus, in acetic acid solution the characteristic potential for  $\text{Na}^+$  ions cannot be derived in the manner proposed by Heyrovsky,<sup>3</sup> unless the potential giving half the diffusion current has a much higher negative value than the corresponding potential in aqueous solutions. This, however, would produce a theoretical difficulty, because the potential of the  $45^\circ$  tangent point (the sharp bend) would have to shift much more upon dilution than would follow

from Heyrovsky's formula. The increase in current density below 2 volts is not quite proportional to the voltage; there is a little more rapid increase between 0.4 and 1.6 volt. This can be attributed to a mercury wave. Mercury could be detected in solution afterwards.

No mercury wave can occur when chlorine ions are present in solution. This was demonstrated in the following way. A solution of  $\text{HgCl}_2$  in acetic acid was shaken with mercury. Then, the solution was decanted

from the heavy precipitate of  $\text{Hg}_2\text{Cl}_2$  into a cell for investigation. The polarogram was taken with the highest sensitivity and again was a nearly straight line, with a very slight slope (Fig. 4). These systems are complicated, however, by the precipitation of calomel in all solutions containing

FIG. 4.

chlorine ions, whenever the voltage is increased above 1.8 volts.

Since the characteristic features in polarograms are only shifted but not changed by varying the concentrations within reasonable limits, it appears desirable to describe these results,

though they are of a qualitative nature only. We wish to extend the investigation to solutions containing several cations and to check the present results quantitatively, giving special attention to the transition from the polarograms of dilute solutions to the more concentrated solutions.

### Summary.

A first report has been given on polarographic investigations with the dropping mercury cathode of solutions of anhydrous acetic acid.

Oxygen does not cause maxima in the complete absence of water.

The polarograms of dilute solutions are practically straight lines, showing no waves or breaks characteristic of the ions in solution.

The polarograms of a more concentrated solution of  $\text{NaCH}_3\text{CO}_2$  show a sharp bend at about 2 volts and a straight continuation above 2 volts. The small wave below 2 volts may be due to mercury.

The polarograms obtained are discussed and compared with the polarograms of aqueous solutions and of the pure solvents water and acetic acid.

My thanks are due to Professor J. Gillis for his kind interest in this work and to the Dutch Committee for intellectual co-operation between the Netherlands and Belgium for a grant.

# THE KINETICS OF THE THERMAL DECOMPOSITION OF ALKYLENE OXIDES. I. ETHYLENE OXIDE.

BY H. W. THOMPSON AND M. MEISSNER.

*Received 3rd July, 1936.*

The desirability of examining the kinetics of the homogeneous thermal decomposition of the vapours of a series of related compounds has recently been frequently emphasised. Hinshelwood and his collaborators have for example studied the relationships with aldehydes and ketones,<sup>1</sup> and with ethers, while Steacie and others have examined the series of alkyl nitrites.<sup>2</sup> Interest in the problem has increased as a result of certain hypotheses which have been suggested with regard to the mechanism of the reactions involved. On the one hand, the intervention of reaction chains in the processes has been considered, free alkyl radicals playing an important part in the propagation of the chains;<sup>3</sup> on the other, there has been the discovery of the segmented nature of the curve connecting the "unimolecular" velocity constant for the decomposition of a particular substance with the initial concentration employed.<sup>4</sup> This result has been interpreted as perhaps being connected with a localisation of the energy of activation in different parts of the same molecule, or with different types of activated state, with the consequence that a decomposition giving similar products may occur via independent mechanisms.

A comparison of the data with a homologous series of aldehydes has proved interesting as a means of suggesting the particular linkages or modes of vibration in which the energy of activation may become localised. It seemed therefore fitting to study the relationships with another series of homologues, the alkylene oxides, many of the simplest of which are very volatile and suitable experimentally. The present paper deals with the simplest member of the series, ethylene oxide. The data for propylene oxide, which shows significant differences of detail, will be given later.

The kinetics of the thermal decomposition of ethylene oxide have been studied previously by Heckert and Mack.<sup>5</sup> The reaction was found to be homogeneous over the temperature range 380-444° C., giving as products carbon monoxide, methane, and a little hydrogen and ethane. Making corrections for a noticeable induction period, the course of the reaction could be represented by a "first order" equation, and over the range of pressure used (100-1000 mm.), the velocity constant was sufficiently independent of initial pressure to indicate an essentially first order process. On the other hand, a "falling-off" with decreasing initial

<sup>5</sup> *J. Am. C. S.*, 1929, **51**, 2706.

concentration was noticed, but not examined in detail. The energy of activation was ca. 52,000 cal.

Heckert and Mack interpreted the induction period as involving, in part, a primary isomerisation to acetaldehyde, and from the retarding influence of many inert gases inferred the presence of reaction chains. A considerable alteration in the surface-volume ratio of the reaction vessel, did not, however, affect the reaction velocity.

On the basis of the data of Heckert and Mack, and assuming that at the highest initial pressures used by them the truly unimolecular course of the reaction had not yet been reached, Ramsperger<sup>6</sup> calculated the number of squared terms between which the energy of activation must be divided, and found it to be greater than 14.

The results given below are in almost complete agreement with those of Heckert and Mack. They go further, however, and provide additional knowledge concerning the mechanism of the reaction. It is possible to measure the rate of the reaction up to temperatures some fifty degrees higher than the highest used by Heckert and Mack, and the complications introduced by the induction period are thereby largely eliminated; the possibility of interference by surface processes is also relatively decreased. More important, however, is the result that the "falling-off" of the velocity constant with decreasing pressure is rather more noticeable at the higher temperatures.

Several theoretical discussions of the reaction have recently been published. Kassel<sup>7</sup> has contended that the mechanism proposed by Heckert and Mack is untenable since the acetaldehyde formed by a primary isomerisation would decompose much more rapidly than actually occurs. Fletcher<sup>8</sup> has suggested that ethylene oxide undergoes two simultaneous primary reactions, one an isomerisation to give acetaldehyde, the other a decomposition to give free radicals, which then catalyse the decomposition of the aldehyde. This interpretation has been treated mathematically by Sickmann,<sup>9</sup> who has thus obtained a qualitative explanation of the induction period and has interpreted the retarding influence of foreign gases as resulting from their power of facilitating the recombination of free radicals. These several hypotheses are discussed below.

### Experimental Method.

The reaction was followed by measurement of the pressure change at constant volume. The apparatus and general procedure were similar to those previously described in the investigation of other similar decompositions.<sup>10</sup> The reaction vessel was a cylindrical pyrex bulb of ca. 250 c.c. capacity, enclosed within an electric furnace. Temperature was measured by means of a platinum-platinum rhodium thermocouple in conjunction with a previously calibrated galvanometer. The reaction vessel was connected to a capillary mercury manometer, and via taps to a vessel containing liquid ethylene oxide, and to other containers of inert gases. The whole system could be evacuated by means of a Hyvac oil pump backing a mercury vapour pump. For the experiments in packed bulbs a cylindrical pyrex vessel containing many lengths of pyrex glass tubing was used, the relative surface-volume ratio of the packed and empty vessels being about eight-fold.

The ethylene oxide was a Kahlbaum product, refractionated in vacuo, the middle fraction being used. A second sample supplied by British Drug Houses Ltd. was fractionated, and gave the same results.

### Products and End-Points.

According to Heckert and Mack, ethylene oxide decomposes, giving exactly 100 per cent. increase in volume. The temperature at which this measurement was made is not recorded, and it is assumed that at all the temperatures used, *i.e.*, up to  $445^{\circ}\text{C}$ ., and for all initial pressures, the pressure is exactly doubled at the completion of the reaction. Our measurements do not agree with this. At low temperatures and with low initial pressures, the pressure increase observed was ca. 100 per cent., but this decreased with increasing temperature or increasing initial pressure, so as to fall to below 80 per cent. at the highest temperatures and with the highest initial pressures. This is apparently to be explained by the occurrence simultaneously with the decomposition of a condensation process, the extent of which is increased as the pressure or temperature is increased. Such concurrent condensation reactions are common to analogous decompositions. A dark solid product is formed in the reaction vessel at high temperatures, which subsequently slowly decomposes. As the analyses given below show, the bulk of the decomposition follows the equation :

A pressure increase of 90 per cent. implies that 95 per cent. of the ethylene oxide decomposed according to this main reaction. For the purpose of the kinetic measurements, it was therefore necessary to construct calibration curves from which the "end-point" could be read off for any initial pressure at a given temperature.

The gaseous products of the decomposition are primarily methane and carbon monoxide, with a little hydrogen and ethane, agreeing with the results of Heckert and Mack.

That the reaction is, to a first approximation at least, uniform over the course of the pressure change, is shown by the analysis of the products at different stages of a run. Table I. shows typical data. Almost negligible traces of unsaturated hydrocarbons are included in the figures given for carbon dioxide.

The "residue" in each case was examined by combustion. The results are summarised in Table II.

The results in each case indicate that the residue is a hydrocarbon  $\text{C}_n\text{H}_{2n+2}$ , *i.e.*, methane or a mixture of methane with hydrogen and ethane with the last two in equal proportions.

(6)	2.7	5.25	2.80

That the alteration in the percentage pressure increase at different temperatures is not, primarily at least, connected with a marked change in the nature of the reaction, but due to different degrees of superposed condensation, is shown by the analysis of the end-products at different temperatures, using the same initial pressure in each case. Table III. gives typical data.

392	50.3	4.65	4.65	40.5

The end-products using different initial pressures at the same temperature were also analysed. The hydrocarbon residue was combusted fractionally, first with copper oxide to estimate hydrogen, and then with oxygen to estimate methane and ethane. From the data of Table IV. it is seen that at the lowest initial pressures there may be a slight increase

in the relative proportions of ethane and hydrogen to methane.

In view of the possibility that the process may involve a primary isomerisation to give acetaldehyde, qualitative tests were made for the latter. The gaseous products were withdrawn at different stages of a run into a large evacuated pipette, and shaken with water. The solution was treated with Schiff's reagent. No trace of acetaldehyde could be detected at any stage of the reaction over the range of temperatures used. This result agrees with that of Heckert and Mack.

FIG. 1.

### The Homogeneity of the Reaction.

The homogeneity of the process was tested by comparison of the rate in a packed and unpacked vessel. In the packed vessel the reaction, which proceeds to almost the same "end-point" as in the empty vessel, is slightly retarded, but the retardation is such as to correspond to only two or three degrees centigrade change of temperature. Fig. 1 shows the period of half-change plotted as a function of pressure at 457° C. in the two vessels respectively. At 300 mm. initial pressure the ratio  $t_{\text{packed}} : t_{\text{unpacked}}$  is 1.15. It is clear

that no appreciable surface reaction is involved, and if noticeably long reaction chains were propagated, a much greater retardation in the packed vessel might be expected.

### The Order of the Reaction over its Course.

The general course of the reaction is exhibited by the curves of Fig. 2. The induction period noticed at lower temperatures by Heckert and Mack is less marked at the higher temperatures. There is no doubt that over its course the reaction follows essentially a first-order law. The constant  $k = \frac{2.3}{t} \log \frac{a}{a-x}$  ( $k$  in  $\text{sec}^{-1}$ , is not, however, strictly constant, but increases slightly in the early stages and falls off in the later stages of a run. In the same way the ratio  $t_1 : t_2$  is not exactly 2, but has a value lying between that of a first and second order change. Table V. gives typical data.

The initial increase in the value of  $k$  is clearly associated with the induction period; the falling-off in the later stages may be due to two causes, either first to the quasiunimolecular character of the decomposition, or secondly to the retarding influence of the products, which may behave like inert gases in the sense described below.

FIG. 2.

The evaluation of what may be taken as the "accurate" value of the quasiunimolecular velocity constant  $k$  is obviously therefore difficult. Heckert and Mack were able to "correct for" the induction period by assuming the primary isomerisation to acetaldehyde, although no experimental evidence for this was forthcoming. This treatment of Heckert and Mack is not entirely satisfactory. In order to account quantitatively for the course of the pressure change over an entire run, and obtain a differential equation to represent the rate in terms of the concentration and certain constants, it would be necessary to take into account all the various factors influencing the rate, a quantitative estimate of some of which is undeterminable. The value of  $k$  becomes fairly steady during the middle part of a run. For the purpose of the considerations of the succeeding sections, this value of  $k$  is taken as representing the "unimolecular" constant. As an indication of the close agreement with the results of Heckert and Mack, they find at  $442^\circ \text{C}$ .,  $k = 0.0011$ ; the present method gives from our data  $k = 0.0012$ .

The value of the reciprocal of the period of half-change might also be taken as representing a measure of the unimolecular velocity constant, although the complex nature of the course of the reaction makes such a procedure rather doubtful. In fact, however, the value obtained for  $k$  by

the above method, agrees well with in general with that calculated from  $\frac{t-2}{t_4} \log 2$ .

### The Relationship between the Value of $k$ and Initial Pressure.

Heckert and Mack noticed a decrease in the unimolecular velocity

constant with decreasing initial pressure, but did not examine it in detail. Table VI. gives the complete data for runs at 462° C.

It is seen that between 400 mm. and 20 mm. there is a decrease of  $k$  by about 30 per cent. The decrease observed by Heckert and Mack at lower temperatures over the same range of pressure was about 20 per cent.

The plot of  $k$  against  $p_0$  (Fig. 3) reveals a relationship between the two quantities more complex than has hitherto been assumed. Above 250 mm.  $k$  is almost independent of  $p_0$ , corresponding to a unimolecular process, although there are signs that  $k$  still tends to rise slightly with increasing pressure. Below 250 mm. initial pressure the plot of  $k$  against  $p_0$  is "segmented" in nature. Between 250-40 mm. there is one roughly "bimolecular" segment, and below 40 mm. at least one other.

The plot of  $1/t_4$  against  $p_0$  gives a curve closely similar in form to that

of Fig. 3, and this result is reproduced at any temperature, but rather more pronounced at the higher ones.

### Temperature Coefficient and Energy of Activation.

Table VII. summarises the value of  $k$  at different temperatures and for each of four different initial pressures. The logarithms of  $k$  are also given.

From the plot of  $\log k$  against  $1/T$  for each pressure the following values for the energy of activation are obtained :

At 400 mm.  $E = 53,000$  cals.

At 50 mm.  $E = 50,000$  cals.

Corrections have been made in each case for the variation of collision frequency with temperature.

### Molecular Statistics.

To a very large extent at least, the decomposition can be regarded as a quasi-unimolecular reaction of the conventional type. The velocity of the reaction in the region of initial pressure above that at which the constant begins to "fall off," is far in excess of that to be expected from the expression (collision frequency  $\times e^{-E/RT}$ ). Assuming that the energy of activation is distributed among  $n$  squared terms,  $n$  can be calculated as follows.

TABLE VI.

Initial Pressure, mm.	$k \times 10^3$ .	Initial Pressure, mm.	$k \times 10^3$ .

492	1.307	—	—	10.1 2.0043	8.7 3.9305

and the energy of activation is 53,000 cal. The number of molecules reacting per c.c. per sec. is thence found to be  $1.3 \times 10^{16}$ .

The number of collisions between molecules per c.c. per sec. at the above temperature and pressure is  $2.5 \sqrt{2} \pi \sigma^2 \bar{u} n^2 = 1.77 \times 10^{28}$ ; the number of activated collisions, assuming two squared terms are involved, per c.c. per sec. is then  $3.7 \times 10^{12}$ . Thus, the discrepancy is about 3500 fold.

Writing  $\frac{(E/RT)^{1/n} - 1}{\frac{1}{2}n - 1} = 3500$ , we find  $n = 8$ . This value is reasonably in agreement with the structure of the molecule, and perhaps more so than the value calculated by Ramsperger from the data of Heckert and Mack.

### The Influence of Added Inert Gases.

It has in the past appeared somewhat surprising that the rates of the homogeneous gaseous decomposition of simple organic molecules such as aldehydes and ketones are, in general, unaffected by the addition of inert gases, especially if "collision" mechanisms underly the process of activation. Hydrogen has been found to possess in some cases the specific power of restoring the rate in the "low pressure bimolecular" region of a quasiunimolecular reaction to the "high pressure unimolecular" value. According to the original chain mechanism of Christiansen and Kramers, inert gases should behave as negative catalysts in the sense that they should lead to a deactivation of activated molecules on collision, but no evidence for such a property has been forthcoming. On the contrary, chain reactions are usually accelerated by the addition of diluent gases, probably since they prevent the diffusion of active centres to the vessel walls where these can be destroyed.

For these reasons, the influence of inert gases upon the rate of the decomposition of ethylene oxide is anomalous. The presence of the reaction products (carbon monoxide and hydrocarbons) or of argon or nitrogen reduces the rate of the decomposition. The effect of the products may contribute towards the observed decrease in the first order constant in the later stages of a run. Our results agree essentially with those of Heckert

and Mack; but a more detailed study is desirable, and only the main outlines will be given.

With pressures of diluent (argon, nitrogen, carbon monoxide) of the same order of magnitude as the pressure of ethylene oxide, the velocity constant is reduced by about 10-20 per cent. There seems to be a rough proportionality between the extent of the retardation and the pressure of added inert gas.

Table VIII. shows the effect of products upon a run at 460° C.;  $p_1$  is the initial pressure of ethylene oxide,  $p_2$  that of products.

Table IX. shows the effect of argon at 460° C.

TABLE VIII.

The addition of hydrogen was found to increase the velocity of the decomposition of ethylene oxide, in agreement with the results of Heckert and Mack. The important result, however, was that with initial pressures of ethylene oxide corresponding to the "bimolecular" region, the rate could be increased to values greater than that in the "unimolecular" region. It is not possible to draw significant conclusions from this, however, since in the presence of hydrogen the main reaction appears to be affected in nature, the "end-point" being different.

### General Discussion.

The decomposition of ethylene oxide is, in broad outline, like other quasi-unimolecular decompositions. The number of squared terms among which the energy of activation must be distributed in order to comply with the measured rate is reasonable. The velocity constant decreases with decreasing initial pressure in the manner recently found in other similar reactions, and this phenomenon suggests that different types of activated state are possible. Until further data are available for other alkylene oxides it may be unwise to develop this hypothesis further.

There are nevertheless certain complications, such as the induction period, or the influence of added inert gases, which indicate that the relationships may not be so simple as the above implies. The hypothesis suggested by Fletcher and developed by Sickmann supposes that

acetaldehyde is formed by isomerisation, and concurrently with it are produced a few free radicals, which catalyse the decomposition of the aldehyde. If this argument is based solely upon the observation that traces of ethylene oxide catalyse the decomposition of acetaldehyde, it cannot be regarded as convincing; for it is now well known that the decomposition of aldehydes is catalysed by many substances of quite different character,<sup>11</sup> some of which cannot give rise to free radicals. It is surprising that if acetaldehyde is at all formed as a major intermediate product in the decomposition of ethylene oxide, no traces of it can be detected analytically. The aldehyde must decompose instantaneously. It is very unlikely that reaction chains of appreciable length are propagated, unless they can be reflected from the vessel walls, which is most improbable. Moreover, independent series of measurements by Patat and Sachsse on the one hand,<sup>12</sup> and Staveley and Hinshelwood<sup>13</sup> on the other, seem to indicate definitely that the free radical mechanisms developed by Rice and Herzfeld<sup>14</sup> and others are not very relevant to many of the reactions for which they were suggested.

Comparison of the present data with the results for substituted alkylene oxides may throw additional light upon the nature of the decomposition.

### Summary.

Measurements on the kinetics of the thermal decomposition of ethylene oxide vapour have been described. The products of the reaction are mainly methane and carbon monoxide. The course of the reaction can be represented approximately by a first order law, but there are certain complications. The unimolecular velocity constant falls off with decreasing initial pressure in the same manner as in other quasi-unimolecular decompositions, and the plot of  $k$  against the initial pressure has a segmented appearance. The reaction is homogeneous, and no evidence can be found of the propagation of reaction chains. The energy of activation at the higher pressures is ca. 53,000 cals, and falls slightly as the initial pressure is lowered.

The results are compared and contrasted with those previously found by Heckert and Mack; and their bearing upon other theoretical discussions of the reaction mechanism is discussed.

We should like to express gratitude to Dr. B. Lambert for his constant help in connection with apparatus, and one of us (M. M.) thanks the Rhodes Trustees for a Scholarship.

# CONDUCTOMETRIC TITRATIONS OF THE ISOMERIC CHROMIC CHLORIDES WITH SILVER NITRATE.\*

BY NORMAN H. LAW.

Received 29th June, 1936.

One of the most interesting and important applications of Werner's Co-ordination Theory concerns the constitution of the isomeric hexahydrates of the chromic chlorides, which are known in three forms, a violet (or blue), a pale green and a dark green form. Although these may be formulated on Werner's theory as  $[\text{Cr}6\text{H}_2\text{O}]\text{Cl}_3$ ,  $[\text{CrCl}, 5\text{H}_2\text{O}]\text{Cl}_2$ ,  $\text{H}_2\text{O}$  and  $[\text{CrCl}_2, 4\text{H}_2\text{O}]\text{Cl}, 2\text{H}_2\text{O}$  respectively, the evidence in favour of the validity of these formulæ is less convincing than in other cases of such isomerism. In support of these formulæ the reaction of the chlorides in aqueous solution with silver nitrate is usually quoted but the results are not unequivocal. Thus Werner and Gubser<sup>1</sup> obtained from 1.152 to 1.173 equivalents of chlorine from the dark green chloride by precipitation with silver nitrate in ice-cold nitric acid solution, whereas theory requires exactly one equivalent. Moreover, Weinland and Koch<sup>2</sup> showed that the proportion of chlorine precipitated depended to a marked extent on the acidity of the solution and on the nature of the anion of the silver salt. The work of Bjerrum,<sup>3</sup> Lamb<sup>4</sup> and Lamb and Fonda<sup>5</sup> established the importance of hydrolytic effects which complicate the reaction of these chlorides in solution and suggest that, if Werner's formulations are correct, the co-ordination sphere possesses an unusual degree of reactivity which is probably fundamental to such industrial arts as the chrome tanning of leather. This reactivity can readily effect the reaction with silver nitrate, especially as this is usually used in excess in analytical work. It is surprising that the less drastic method of conductometric titration has not been used hitherto.

## Experimental.

The violet chloride was prepared by the method of Bjerrum (found Cr 19.51 per cent., Cl 39.92 per cent.; calc. Cr 19.52 per cent., Cl 39.93 per cent.). The pale green chloride was also prepared by the method of Bjerrum (found Cr 19.59 per cent., Cl 39.69 per cent.), and the dark green salt according to the directions of Werner and Gubser (found Cr 19.82 per cent., Cl 39.94 per cent.).

A modification of the conductivity cell designed by Robbins<sup>6</sup> was used in the course of this work, it being very suitable for titrimetric work. The main feature of the cell was rigidity of the electrode supports, secured by means of a glass bar *not* immersed in the solution. The apparatus is shown

in Fig. 1. The titrant is delivered from a burette into the side-arm T, the major portion of the solution being in the vessel E. By means of alternate gentle suction and pressure exerted through the side-tube A, the added solution can be thoroughly mixed with the main body of liquid.

All conductivity measurements were made on solutions 0.005 *M* with respect to chromium and unless otherwise recorded the temperature was 1.5°, at which the three chlorides were comparatively stable in dilute solution; nevertheless, titrations were performed without undue delay. All conductivity measurements were corrected for dilution by multiplication by the factor (volume of original solution + added titrant)/(volume of original solution), *i.e.*, all conductivities are referred to a constant volume of solution.

FIG. 1.—Conductivity cell for titration work (approximately  $\frac{1}{4}$  natural size).

ionized chlorine and this was confirmed by gravimetric analysis of the precipitable chlorine in solutions buffered at different  $p_H$  values, the following values being obtained:

$p_H$	0.7	1.0	1.7	3.0	4.0
per cent. Cl pptd.	34.5	40	37	56	93

**Conductometric Titrations with Silver Nitrate.**—Fig. 2 shows the conductivity curves obtained at 1.5° during the titration of 0.005 *M* solutions with 0.1 *N* silver nitrate. The initial molecular conductivities were 185.8, 119.1 and 57.1 mhos. respectively. Breaks occurred corresponding to 3.0, 2.1 and 1.54 equivalents of chlorine and in each case the ascending part of the curve after the break always corresponded to the calculated curve for an excess of silver nitrate. The superiority of conductometric titration over gravimetric analysis of the precipitable chlorine can be seen from the fact that from the pale green salt, nearly all the chlorine was precipitated by the addition of a bulk amount of reagent in

### Experimental Results.

**Van't Hoff Factor.**—Cryoscopic determinations using 0.05 *M* solutions gave a Van't Hoff Factor of 3.40, 2.73 and 1.95 for the violet, pale green and dark green salts respectively. The isopiestic vapour pressure method<sup>7</sup> applied to the violet salt gave 3.89 in 0.3 *M* solution and 3.75 in 0.6 *M* solution.

**Quantitative Precipitations with Silver Nitrate.**—By boiling any of these chlorides with silver nitrate solution in the presence of nitric acid three equivalents of chlorine are precipitated. From an acid-free, ice-cold solution of the pale green chloride silver nitrate precipitates 85 per cent. of the total chlorine, the remaining 15 per cent. being precipitated on warming with a little nitric acid. Direct precipitation from ice-cold solution of the dark green chloride gave 88 and 90 per cent. of the total chloride in acid-free solution, and 34 and 40 per cent. in dilute nitric acid solution. These figures, combined with the observation of Weinland and Koch that the nature of the anion of the silver salt had a profound influence on the amount of chlorine precipitable led us to suspect that the  $p_H$  value of the solution was an important factor in determining the amount of

<sup>7</sup> Robinson and Sinclair, *J. Amer. Chem. Soc.*, 1934, 56, 1830.

excess, whilst the more cautious addition of silver nitrate during conductometric titration gave a break at a point only slightly beyond the theoretical.

A similar titration of the violet salt was carried out at 25°, the initial molecular conductivity of 359 mhos. falling linearly to 354 mhos. when 3 equivalents of silver nitrate had been added, when a sharp break occurred and the conductivity rose at the rate calculated for excess of silver nitrate.

Since conductometric analysis was found to be superior to direct gravimetric analysis in the case of the pale green salt, the precipitations

FIG. 2.—Conductometric titration of 50 c.c. of 0.005 *M* chromium chlorides with 0.1 *N*- $\text{AgNO}_3$ .

from solutions of the dark green salt in buffered solutions were repeated, with conductometric analysis. Fig. 3 gives the curves obtained for seven such solutions as follows:

$p_{\text{H}}$	Buffer.	End point.
2.3	Solution + nitric acid	1.00 equiv.
3.0	" " "	1.00
3.6	Citric acid - $\text{Na}_2\text{HPO}_4$	1.05
4.0	" " "	1.11
4.3	" " "	1.20
4.6	" " "	1.24
5.0	Citric acid - Sodium citrate	2.0

Separate experiments showed that the buffer solutions did not precipitate a silver salt. In Fig. 3 the scale of the ordinate on the graph has been adjusted in each case, so that each curve starts at the same initial value. These curves are very significant. A few experiments were carried out with buffered solutions of the other two chlorides. The end-points for the violet salt do not appear to be influenced by the  $p_{\text{H}}$  of the solution,

titrations at  $p_H$  3 and 5 giving curves of the same type as that for the violet chloride in Fig. 2. This was also true of the pale green salt at  $p_H$  3, but at  $p_H$  4, although a break was found at 2 equivalents, the slope of the curve

FIG. 3.—Conductometric titration of 0.005  $M$   $[\text{CrCl}_2 \cdot 4\text{H}_2\text{O}]\text{Cl}$  with 0.1  $N$   $\text{AgNO}_3$  in buffered solutions.

on further addition of silver nitrate was less than the theoretical, showing that slight precipitation was still in progress. This was more marked at  $p_H$  5 in which case a second break was found at 3 equivalents, the form of the curve being similar to that for the dark green salt at  $p_H$  5 shown in Fig. 3.

### Discussion.

For all three salts both the Van't Hoff Factor and the molecular conductivity support the formulations accorded on Werner's theory. That the violet salt dissociates into three chloride ions is also shown by the fact that it always gives three precipitable chlorine atoms and the curve in Fig. 2 shows that there is no discontinuity in the curve such as might be expected if precipitation occurred in stages. Moreover, the amount of chlorine precipitated is independent of the  $p_H$  value of the solution, at least between  $p_H$  3 and 5. The replacement of chloride ions

by nitrate ions proceeds with little change in conductivity, consistent with the very similar mobilities of these two ions. There seems, therefore, to be no doubt as to the constitution of this chloride.

In the case of the pale green salt, the conductometric curve in Fig. 2 shows that the salt has two ionised chlorine atoms, but a slight attack on the third co-ordinated chlorine atom occurs during precipitation witnessed by the break at 2.1 equivalents and the slight increase in conductivity during precipitation. This must be accounted for by any adequate theory, as well as the fact that the reactivity of this third chlorine atom is favoured at high  $p_H$  values and repressed at low  $p_H$  values.

The dark green chloride in aqueous solution gives an anomalous conductivity curve with a break at 1.54 equivalents, together with a considerable increase in conductivity during precipitation, showing that the co-ordinated chlorine atoms are much more loosely bound. In acid solution, however, the salt behaves as a uniunivalent electrolyte, the co-ordination sphere being more readily attacked as the  $p_H$  value increases. At the same time the curve for excess of silver nitrate departs more and more from the theoretical value and a second break appears in the vicinity of 2 equivalents. At  $p_H$  5 the first break has been smoothed out and another appears at 3 equivalents, but it should be noted that the conductivity at this point does not correspond to a trivalent salt; rather is it characteristic of a bivalent salt. As the  $p_H$  of the unbuffered solution is 4.75, the break at 1.54 equivalents in Fig. 2 cannot be given especial significance. Of greater importance is the fact, that, provided the  $p_H$  value of the solution is suitably adjusted, the formal proof of the constitution of these salts is complete.

Nevertheless, there remains much to be explained, particularly the progressive attack of the second chlorine atom of the dark green chloride as precipitation proceeds in an unbuffered solution and the increasing reactivity of this atom as the acidity is decreased together with the reactivity of the third chlorine atom at high  $p_H$  values. These reactions must depend on a most complex series of hydrolytic reactions, in which substitution of either hydroxyl ions or water molecules within the co-ordination sphere can occur and it does not seem wise to attempt any further explanation until more knowledge of these hydrolytic reactions is available.

### Summary.

Conductivity titrations of the reaction between silver nitrate and each of the three isomeric chromic chlorides are described and it is shown that a conductometric investigation is superior to a direct gravimetric analysis of precipitable chlorine.

The violet chloride undoubtedly yields three ionised chlorine atoms and the pale green two chlorine atoms, except in solutions of  $p_H$  value in the vicinity of 5 when the third atom is easily precipitated.

The dark green salt is much more reactive. A formal proof of its constitution results from work in very acid solution, but as the  $p_H$  is increased the second and, at high  $p_H$  values, the third chlorine atom becomes precipitable.

The author wishes to offer his sincere thanks to Dr. R. A. Robinson for his advice and encouragement in the course of this investigation.

# THE PHOTOCHEMISTRY OF NITRATES, NITRITES AND NITRO-COMPOUNDS. II.

BY C. H. PURKIS AND H. W. THOMPSON.

Received 9th June, 1936.

We have recently undertaken a systematic study of the photochemistry of nitrates, nitrites and nitro-compounds. The ultraviolet absorption spectra of some of these compounds have previously been described.<sup>1</sup> Melvin and Wulf have simultaneously reported spectral measurements from which they have attempted to attribute a banded absorption in the near ultraviolet in mixtures of nitric oxide, nitrogen peroxide and water vapour to the carrier molecule HONO.<sup>2</sup> The data previously given by us substantiate the argument of Melvin and Wulf strongly, and interesting conclusions can be drawn from a comparison of the two sets of data. In the present paper these conclusions are outlined, and further spectral measurements for other related compounds are given. The qualitative course of the photochemical decomposition of nitrites is also discussed.

## Experimental Details.

The instruments used in measuring the absorption spectra were as previously described. In addition, some visual measurements were made with a small constant deviation glass spectroscope.

The photochemical changes were followed by a method essentially the same as described by Thompson and Linnett.<sup>3</sup> The radiation from a mercury lamp was condensed by passing through a transparent quartz spherical flask containing either water or a solution filter, and then directed upon the reaction cell. Pressure changes were followed manometrically. In some experiments the reaction vessel was enclosed within a water thermostat having a large quartz window at the side.

Methyl, ethyl and *iso*-amyl nitrites were prepared as before. Secondary butyl nitrite

$\text{CH}_3 \cdot \text{CH}_2 \cdot \text{CH}(\text{CH}_3) \cdot \text{O} \cdot \text{NO}$  was obtained by the action of nitrous acid upon secondary butyl alcohol. The nitrite layer, which is insoluble in water, was separated, dried and purified by fractional distillation *in vacuo*.

Nitroso-chloro-propane  $\text{CH}_3 \cdot \text{CH}(\text{NO}) \cdot \text{CH}_2\text{Cl}$  was prepared by the method of Ponzio<sup>4</sup> by leading a stream of chlorine over a solution of acetoxime in 10 per cent. caustic soda solution. The chloro derivative separated as a dark blue liquid which was dried over calcium chloride and subsequently fractionated *in vacuo*. It was stored over ice since it is liable to decompose at room temperatures.

N-methyl O-methyl hydroxylamine  $\text{CH}_3 \cdot \text{N}(\text{H}) \cdot \text{OCH}_3$  was prepared by the method of Jones.<sup>5</sup> N-methyl N-methoxy urethane was first prepared by

<sup>1</sup> *Far. Soc. Trans.*, 1936, **32**, 674.

<sup>2</sup> *J. Chem. Physics*, 1935, **3**, 755.

<sup>3</sup> *J. Chem. Soc.*, 1935, 1452.

<sup>4</sup> *Chem. Zentralblatt*, 1906, **10**, (1), 1692.

<sup>5</sup> *Am. Chem. J.*, 1898, **20**, 43.

the methylation of hydroxy-urethane, the latter being formed from the interaction of hydroxylamine and chloroformic ester. The product was then heated in a sealed tube with concentrated hydrochloric acid, and distilled with potash to liberate the free base, which was purified by fractional distillation *in vacuo*.

Dimethyl nitrosamine was prepared by the method of Renouf<sup>6</sup> and diethyl nitrosamine by that of Geuther.<sup>7</sup> Both methods depend essentially upon the action of nitrous acid upon a secondary amine.

## Results.

### (1) Spectral Data.

In Part I the ultraviolet absorption spectra of methyl nitrite, methyl nitrate and nitro-methane and the corresponding ethyl derivatives, were described. As then explained, the nitrites show a system of diffuse bands in the near ultraviolet; the intensity distribution within individual bands of the system is peculiar, and moreover different from one band to another. In view of the considerations of the nitrous acid spectrum given below, it became desirable to attempt to measure with as great an accuracy as possible the wavelength of the "origin" of each band. The nature of the band obviously makes such a measurement difficult, but the values previously given for the "centres" of the bands have now been revised, and the corrected values are given below.

(i) *Methyl Nitrite*.—The spectrum is represented diagrammatically in Fig. 1 (a), the wave-numbers of the bands being given.

(ii) *Ethyl Nitrite*.—Fig. 1 (b) similarly shows the system of bands observed. As with methyl nitrite, the most intense bands have no marked head, and two broad bands are noticed at the long-wavelength end of the system; these two bands appear at first sight to be distinct from the remainder of the system.

(iii) *Iso-amyl nitrite*.—The absorption of the vapour of this substance is very similar to that of both methyl and ethyl nitrites. The band system in the near ultraviolet is shown in Fig. 1 (d). Each band is diffuse and there is not definite degrading in either direction. The two longest wavelength bands have not, however, the abnormally broad nature of those of methyl and ethyl nitrites just referred to.

(iv) *Sec-butyl nitrite*.—As with the above compounds, there is a system of diffuse bands between 4000-3000 Å. and a continuous absorption at shorter wavelengths. At higher pressures the continuum extends to longer wavelengths and eventually overlaps the bands system. The latter is shown diagrammatically in Fig. 1 (c). The striking difference between this system of bands and each of the above is that each of the bands of butyl nitrite degrades to the red and has a distinct head on the short-wavelength side.

(v) *Dimethyl nitrosamine*.—The ultraviolet absorption is very similar to that of the nitrites. Between 3900-3200 Å. is a system of diffuse bands with no marked head, and at shorter wavelengths a region of continuous absorption which extends to longer wavelengths as the pressure is increased. The approximate wavelengths of the "centres" of the most intense bands are 3768, 3645, 3522, and 3305 Å.

(vi) *Diethyl nitrosamine*.—The spectrum is similar to that of dimethyl nitrosamine, except that the narrow region of absorption between 4000-3200 Å. has not been clearly resolved into bands.

(vii) *N-methyl O-methyl hydroxylamine*.—There is continuous absorption from about 2500 Å. to shorter wavelengths.

(viii) *Nitrosochloropropane*.—This compound, which is deep blue in colour in the liquid state has a region of absorption in the red about 7500-5260 Å., and a second region of continuous absorption at wavelengths

<sup>6</sup> *Ber.*, 1880, 13, 2170.

<sup>7</sup> *Ann.*, 1863, 128, 151.

shorter than about  $2400 \text{ \AA}$ . The first region has not been resolved into bands, but the dispersion used was small.

## (2) Photochemical Data.

(a) *Methyl nitrite*.—When the vapour of this substance is irradiated with the unfiltered light of a mercury vapour lamp, a decrease in pressure

FIG. 1.

occurs. The decrease is at first linear with time, but falls off in the later stages. When the reaction is apparently complete, as indicated by no further pressure change, the decrease is about 37 per cent. of the initial pressure. (An appreciable dead-space error has not been allowed for.) Table I summarises a typical run.

At the beginning of a run there was usually a pressure increase of a few millimetres suggesting a slight induction period, but this may have been due to a minor heating effect. Preliminary drying with phosphorus pentoxide did not affect the general course of a run.

During the progress of a run a white solid was deposited on the back face and sides of the cell, but with the reaction cell in air none was deposited on the front face. This observation may be significant, and is discussed below.

The solid deposit was first examined. It was insoluble in water, but dissolved in concentrated nitric acid. A suspension in water was examined by Schryver's test for formaldehyde. The magenta colour produced suggested that the solid contained paraformaldehyde. The following sensitive reaction confirmed this result. A sample of the solid was warmed with concentrated sulphuric acid, and a rod previously dipped in benzene was held in the vapours. A deep red colour was produced.

The solid deposit had an unpleasant smell and since the aqueous washings of the reaction cell were acidic, formic acid was indicated. A solution of silver nitrate was gradually darkened and silver deposited by the aqueous extract, which supports this conclusion.

The gaseous products were withdrawn into a gas-holder over mercury. Apart from a small amount of unchanged methyl nitrite, possible constituents might be carbon monoxide, hydrogen, nitrogen, nitrous oxide, nitric oxide, carbon dioxide, and oxygen. The accurate analysis of such a mixture is very difficult. Several procedures were adopted. In the first, the gas mixture was separated into two fractions, (i) condensable in liquid air, (ii) not condensable by liquid air. Table II shows the results of six analyses, each sample being taken from an independent run.

TABLE I.—INITIAL PRESSURE

1972	150
2200	157
2600	162
2899	165
2941	165

TABLE II.

Run No.	1	2	3	4	5	6	Mean.
Percentage condensed	49.5	50.1	50.2	45.2	49.8	56.1	50.1
Percentage not condensed	50.5	49.9	49.8	54.8	50.2	43.9	49.9

It is seen that the proportions of condensable and non-condensable products are roughly equal.

The non-condensable fraction might be expected to contain nitrogen, oxygen, carbon monoxide, and hydrogen. Absorption with alkaline pyrogallol ammoniacal cuprous chloride, and subsequent combustion showed that carbon monoxide were present only in small amount (about 5 per cent. of the total fraction) and oxygen only in traces. The bulk of the non-condensable fraction appeared to consist of nitrogen.

The condensable fraction was slowly but almost completely dissolved in water, which suggested the presence of considerable quantities of nitrous oxide. This was confirmed by a very rapid absorption of about 90 per cent. of the gas by absolute alcohol. The residue contained a small amount of combustible gas, but its exact nature could not be ascertained. The

residue also contained traces of nitric oxide, which turned saturated ferrous sulphate brownish.

It is therefore concluded that the gaseous products in the photo-decomposition of methyl nitrite vapour contain about 45 per cent. nitrogen, 45 per cent. nitrous oxide, small amounts of carbon monoxide and hydrogen and traces of other gases.

(b) *Ethyl nitrite*.—On illumination of gaseous ethyl nitrite with the full radiation of a mercury lamp, there is a pressure decrease which follows the same general course as with the methyl nitrite above, but this decrease is only about 30 per cent. of the initial pressure, *i.e.* smaller than with the latter substance. With ethyl nitrite therefore there is produced either less solid vapourless product, or more gaseous products, than with methyl nitrite.

Drops of a faintly yellow liquid remained in the cell at the end of a run. This liquid was acidic, and when tested with Schiff's reagent for the presence of aldehydes it gave a positive result.

The gaseous products were withdrawn and analysed as before in the case of methyl nitrite.

TABLE III.

Run No.	1	2	3	Mean.
Percentage condensed .	35.3	40.6	40.4	38.8
Percentage not condensed .	64.7	59.4	59.6	61.2

For three runs the runs shown in Table III were obtained.

Thus the proportion of non-condensable gases is greater than with methyl nitrite.

The condensable fraction was nearly completely soluble in alcohol, leaving a small combustible residue which appeared to be primarily methane. The non-condensable fraction contained some carbon monoxide and a little methane but was mainly nitrogen. The total percentage composition of the gaseous products for three typical runs is given in the following table:—

TABLE IV.

	Run 1.	Run 2.	Run 3.	Mean.
Nitrogen percentage .	39.3	37.6	38.3	38.4
Nitrous oxide percentage .	25.7	32.1	32.9	30.2
Carbon monoxide percentage .	22.2	17.0	15.3	18.1
Methane, etc., percentage	12.8	13.3	13.5	13.2

It is seen that the principal constituents are again nitrous oxide and nitrogen, but these are not present in exactly equivalent proportions. The ratio of carbon monoxide to "methane" is also not unity. An interpretation of these facts is suggested below.

### Discussion.

From a spectroscopic standpoint the most interesting considerations relate to the system of bands shown by the nitrites in the near ultra-violet. From a comparison of the nitrites with nitrates and nitro-compounds it was previously suggested that this band system was shown exclusively by compounds containing the  $\text{—N=O}$  group. The present work supports this conclusion (*e.g.* the bands are absent with the substituted hydroxylamine). In Fig. 1 the positions of the nitrite bands

for the different compounds are shown. The bands of dimethyl nitrosamine, which are somewhat more difficult to measure, lie at closely similar wavelengths.

The above conclusion can, however, be taken further: the tertiary nitroso-compound, nitroso-chloropropane, does not give a corresponding absorption in the same near ultraviolet region. It thus appears that the system of bands between 3000-4000 Å. is characteristic of compounds in which the  $\text{—N=O}$  group is attached to an atom having free electrons, as in  $\text{—O—N=O}$ , or  $\text{>N—N=O}$ . The possibility of resonance in such

structures, which may be representable by  $\text{—}\overset{\text{O}}{\underset{|}{\text{O}}}\text{—N}=\overset{\text{O}}{\text{O}}$  and  $\text{>}\overset{\text{O}}{\underset{|}{\text{N}}}\text{—N}=\overset{\text{O}}{\text{O}}$ ,

may have some bearing upon this. If the level of the tertiary nitroso-compound at about 6500 Å. corresponds to the near-ultraviolet level of the nitrites, but is displaced in the latter substances as a result of resonance phenomena, we might take the difference in energy between the level in the two cases as representing the resonance energy of the  $\text{—O—N=O}$  structure. This will be roughly  $3700 \text{ Å.} \cdot 6500 \text{ Å.} \equiv (27,000 - 15,400) \text{ cm.}^{-1} = 11,600 \text{ cm.}^{-1} \equiv 1.44 \text{ volt} \equiv 33 \text{ kcal. per gm. mol.}$  On this hypothesis the difference between the lowest level of the tertiary nitroso-compounds on the one hand, and the nitro-compounds on the other, may represent the resonance energy of the nitro-group. This will be roughly  $(40,000 - 15,400) = 24,600 \text{ cm.}^{-1} \equiv 70 \text{ kcal. per gm. mol.}$  Some doubt, however, is cast upon this interpretation, since the difference in energy between the lowest levels of the nitrites and nitrates, which might also perhaps be associated with resonance in the nitro-group, is only 37 kcal.; but the complex nature of the nitrate structure may be the reason for the discrepancy.

It is clear that in all the nitrites the main vibration frequency excited in the band region is about  $1000 \text{ cm.}^{-1}$ , decreasing noticeably to higher levels. Comparison with known valency vibrations of similar compounds containing atoms of similar mass, shows that it is reasonable to assign the frequency 1000 to a valency vibration in the nitrite molecule.\*

It is interesting to correlate the above data with those of Melvin and Wulf for nitrous acid. The excited level of this compound agrees well with those of the alkyl nitrites. The frequency interval between the more intense bands (ca  $1000 \text{ cm.}^{-1}$ ) implies too that this frequency involves the same vibration as is excited in the alkyl nitrites. The interpretation of the feebler bands of nitrous acid is less obvious. Of many possible hypotheses, two appear most probable, each differing from that suggested by Melvin and Wulf. These are best explained with the help of Fig. 2.

According to Fig. 2 (a) the satellite bands are interpreted as being due to vibration levels superposed upon the main vibration levels. The magnitude of the superposed vibration is about  $250 \text{ cm.}^{-1}$ , and of the order of a deformation oscillation. It may be reasonable to suppose that with the molecule  $\text{H—O—N=O}$  such a deformation is more excitable by virtue of the nature of the light H atom, whereas with the heavier alkyl radicals this is impossible. On the other hand, there seems to be no reason why deformation vibrations should not be excited above the two

\* For example, the frequencies of the molecule  $\text{N} \equiv \text{N} = \text{O}$  are given as 2224, 1285 and 589; of  $\text{Cl—C} \equiv \text{N}$  as 729, 2201 and 397; and of  $\text{Cl—N} = \text{O}$  as 923, 1832 and 633.

lowermost excited vibration levels. Also the value  $250\text{ cm}^{-1}$  is perhaps rather lower than might have been expected for the deformation oscillation frequency.

The alternative hypothesis involves the assumption that two vibration levels are excited, one about  $1000\text{ cm}^{-1}$ , the other about  $2250\text{ cm}^{-1}$ . The satellite bands are thus interpreted as combinations of the two normal frequencies (Fig. 2 (b)).

FIG. 2.

The spectroscopic data suggest that the primary act in absorption of ultraviolet frequencies by the nitrites is a dissociation process, since the bands are diffuse under high dispersion. The analytical results suggest that the primary process is represented in general by :

e.g. for methyl nitrite,

The subsequent changes are somewhat different for the different nitrites, but, in general, decomposition of the hyponitrous acid leads to much nitrogen and nitrous oxide.

With methyl nitrite the formaldehyde first formed polymerises thermally or photochemically to give solid paraformaldehyde. Carruthers and Norrish<sup>8</sup> have studied the photochemical polymerisation of formaldehyde and shown that it is catalysed by traces of formic acid, the solid polymer being deposited preferentially on a cold surface. As explained above, traces of formic acid were detected among the end-products. This might well arise from an oxidation of a little formaldehyde by the decomposition products of the hyponitrous acid. These facts taken together suggest why the deposition of the polymer occurs only on the back face of the cell unless the latter is cooled uniformly.\*

The traces of carbon monoxide and hydrogen found among the decomposition products of methyl nitrite presumably arise from a photochemical decomposition of formaldehyde.

With ethyl nitrite we should expect the primary products to be acetaldehyde and hyponitrous acid. Photo-polymerisation of acetaldehyde does not occur as easily as with formaldehyde, and is not catalysed in the presence of acetic acid. We might therefore expect to obtain a much smaller pressure decrease in the run than with methyl nitrite. Actually the decrease in pressure is smaller, though not markedly. It seems probable that some of the acetaldehyde is decomposed giving methane and carbon monoxide, and some is oxidised by the decomposing HNO to give the drops of liquid acetic acid, which in turn dissolve some acetaldehyde. The part played by the HNO in oxidising the aldehyde may be more significant here than in the case of methyl nitrite, and lead to a ratio nitrogen : nitrous oxide appreciably different from unity.

The above mechanism agrees with that suggested by Anderson, Crumpler and Hammick for the photolysis of more complicated organic nitroso compounds.<sup>9</sup> It should be possible to test the hypothesis by a consideration of other examples, *e.g.* *iso*-amyl nitrite,

Such work is now in progress. Preliminary experiments show that on illumination of this substance with the light of the mercury lamp, an increase of pressure is observed, which can be reconciled with the mechanism suggested for the decomposition.

\* *Far. Soc. Trans.*, 1936, 32, 195.

\* A microanalysis of the solid polymerised product gave C 38.19 per cent., H 6.84 per cent., O 54.97 per cent. This corresponds to the empirical formula  $\text{C}_{3.182}\text{H}_{6.706}\text{O}_{3.437}$ . Assuming the non-branching mechanism of Norrish and Carruthers the formula of the product should be  $\text{C}_{n+3}\text{H}_{4n+4}\text{O}_{n+3}$ ,  $n$  being the chain length for the photopolymerisation of formaldehyde in the presence of formic acid. It is likely that the water formed in the final chain-breaking link will be occluded in the solid product. We could then correct the formula of the latter to  $\text{C}_{3.182}\text{H}_{6.276}\text{O}_{3.182}$ . Then

$$\frac{2n+4}{n+3} = \frac{6.276}{3.182} \text{ whence } n = 68.$$

It may, however, be unwise to attach too much significance to this calculation since small errors in the microanalytical work may considerably affect the value of  $n$  obtained.

<sup>9</sup> *J. Chem. Soc.*, 1935, 1679.

If the mechanism now suggested for the photo-decomposition of the nitrites is correct, it is interesting to contrast it with that which has been suggested as the primary stage in the thermal decomposition of these substances, namely, according to Steacie and his collaborators,

#### Summary.

Previous measurements on the photochemistry and spectroscopy of nitrates, nitrites and nitro compounds have been extended. A comparison is made with the data for nitrous acid recently reported by other workers, and interpretations are suggested to explain the structure of the regions of banded absorption in the nitrite spectra. The products of photochemical decomposition of the nitrites are described, and a mechanism is suggested to represent in general the course of this reaction.

We are grateful to the Government Grant Committee of the Royal Society for assistance in the purchase of instruments.

## FREE AND TOTAL SURFACE ENERGIES AND RELATED QUANTITIES.

BY ALLAN FERGUSON, M.A., D.Sc., and S. J. KENNEDY, M.Sc.,  
A.Inst.P. (Queen Mary College).

*Received 24th June, 1936.*

The object of the present investigations is primarily to compute the values of the free and total surface energies of super-cooled liquids at the absolute zero, and to discuss their dependence on constitution and their relation to other physical constants. In the examination of the literature it became evident that large gaps existed in our knowledge of other surface tension constants and it is a second object of this paper to fill in these gaps where possible. It should be emphasised at the outset that the possibility of obtaining figures for surface energies depends on the existence of reliable data giving the surface tensions of pure liquids at different temperatures.

These data, in all instances, form the *terminus a quo*, and it is not till one makes a search into the literature that one realises how scanty are the relevant data. There are determinations in plenty of the surface tensions of isolated substances, at one or two not very widely separated temperatures. What is needed, however, for the purposes of such investigations as this, is a set of tables which shall give the surface tensions over a wide range of temperature, of different series of related organic compounds—esters, ethers, ketones and the like—where special attention has been paid to the purification of the specimens and to the trustworthiness of the surface tension method. It is hoped that one or two of these gaps will be filled in the near future.

Taking, however, the published figures as they stand, and selecting

therefrom what appear to be the most accurate results, the authors have calculated the following constants for the different substances listed :

(i) The value of the constant  $\gamma_0$  and the exponent  $n$  in the power law connecting surface tension and temperature

$$\gamma = \gamma_0(1 - m)^n$$

( $m$  here stands for reduced absolute temperature and  $\gamma_0$  is the surface tension of the super-cooled liquid at the absolute zero).

(ii) The value of the exponent  $p$  in a generalised form of Macleod's equation

$$\gamma = C(\rho_L - \rho_V)^p$$

(iii) The value of  $E_0$  (or  $e_0$ ) the total or the free molecular surface energy of the super-cooled liquid at the absolute zero.

Having obtained these quantities it becomes possible to investigate their dependence on chemical constitution and their relation to other physical constants of the liquid. The present paper is concerned chiefly with the listing of these data—only a tentative discussion is given of the related matters.

The figures of primary importance are those for *surface tension and temperature*. These data being critically selected, either or both of two methods may be followed. The critical temperature being known, a logarithmic plot of  $(1 - m)$  and  $\gamma$  suffices to determine the required constants  $\gamma_0$  and  $n$ . Or the equation may be attacked by the method of least squares (or some related method), labour being reduced by employing mechanical aids to computation.<sup>1</sup> We have found it convenient to follow both these methods. The graphical method, though less precise, indicates very clearly to the eye whether the power law is or is not closely followed.

It should be noted that, even if the critical data are not available, it is possible, without much difficulty to evaluate  $b$ ,  $\gamma_0$  and  $n$  in the equation

$$\gamma = \gamma_0(1 - b\theta)^n$$

where  $b$  is the reciprocal of the critical temperature. Thus, if, by interpolation methods,  $d\gamma/d\theta$  is found for different values of  $\theta$ , the quantity  $\gamma \cdot d\theta/d\gamma$  is linear in  $\theta$ , and a plot of these two variables determines  $n$  and  $b$ . The value of  $\gamma_0$  may then be obtained from the original equation.

The values of  $\gamma_0$  and  $n$  having been determined it becomes possible to calculate the total energy ( $\lambda$ ), which is given by

$$\lambda = \gamma - m \cdot \frac{\partial \gamma}{\partial m} = \gamma_0(1 - m)^{n-1} \cdot \{1 + m(n - 1)\},$$

so that values showing the magnitude of  $\lambda$  at any required temperature may be obtained from the values of  $\gamma_0$  and  $n$  listed in this paper.

The parachor  $P$ , is usually defined as the value of  $M \cdot \gamma^{1/3}/(\rho_L - \rho_V)$ . This definition is convenient, inasmuch as the parachor may then be obtained from one determination of a surface tension and a density—the expression just given being, of course, independent of the temperature if Macleod's law is followed. Actually many unassociated substances follow a generalised form of Macleod's law in which

$$\gamma = C(\rho_L - \rho_V)^p$$

<sup>1</sup> In our calculations, the work was considerably expedited by the use of a "Nova Brunsviga" calculating machine.

and  $p$  which is constant for any one liquid varies from liquid to liquid, and is, in many instances, sensibly different from 4. The assumption of the "fourth power law," leads in these instances to values of the parachor which show a sensible drift with temperature—a drift which disappears when the appropriate value of  $p$  is chosen, and the parachor  $P$  computed from

$$P = M \cdot \gamma^{1/p} / (\rho_L - \rho_V) = MC^{1/p}$$

where  $C$  is the constant of Macleod's equation in its general form.

If, following Katayama, we define the free molecular surface energy ( $e$ ) as  $\gamma \cdot \frac{M^{\frac{1}{2}}}{(\rho_L - \rho_V)^{\frac{1}{2}}}$ , instead of  $\gamma \cdot \frac{M^{\frac{1}{2}}}{\rho_L^{\frac{1}{2}}}$ , with a similar expression for the total molecular surface energy ( $E$ ) in which  $\lambda$  replaces  $\gamma$ , it is not difficult to arrive at expressions which give, very accurately, the march of these quantities with temperature.

It is convenient to take the equations

$$\gamma = \gamma_0(1 - m)^n \text{ and } \gamma = C(\rho_L - \rho_V)^p$$

as fundamental. They are the simplest expressions connecting the fundamental quantities surface tension, density and temperature, they are easily tested graphically or algebraically, and the constants  $\gamma_0$ ,  $C$ ,  $n$  and  $p$  are readily and accurately calculable. In terms of these constants we at once find

$$e = \gamma \cdot \frac{M^{\frac{1}{2}}}{(\rho_L - \rho_V)^{\frac{1}{2}}} = e_0 \cdot (1 - m)^{n - \frac{2n}{3p}}$$

where

$$e_0 = \gamma_0^{1 - \frac{2}{3p}} \cdot (MC^{1/p})^{\frac{1}{2}} = \gamma_0^{1 - \frac{2}{3p}} P^{\frac{1}{2}},$$

where  $P$  is the parachor.

Similarly,

$$E = \frac{\lambda M^{\frac{1}{2}}}{(\rho_L - \rho_V)^{\frac{1}{2}}} = E_0(1 - m)^{(n - \frac{2n}{3p} - 1)} \{1 + m(n - 1)\},$$

where  $E_0 = \gamma_0^{1 - \frac{2}{3p}} P^{\frac{1}{2}}$ , and we see, therefore, that  $E_0 = e_0$ .

As the figures will show,  $n$  does not vary greatly from liquid to liquid, and for rough computations may be assumed to be constant at the value 1.2. If in addition we assume, as in the ordinary parachor calculations that  $p = 4$ , we find—

$$e = e_0(1 - m) \text{ and } E = E_0\{1 + 0.2m\},$$

as was pointed out by Katayama. It would seem, then, that the curves between these quantities and the temperature are rectilinear, starting from the same point at the absolute zero,  $e$  diminishes to zero at the critical temperature, while  $E$  increases to a maximum at the critical temperature. This does not seem plausible, and the fact is that for practically all the substances which we have examined, the index  $(n - \frac{2n}{3p})$

is a little greater than unity, so that  $(n - \frac{2n}{3p} - 1)$  is a little greater than zero. The effect of the power term in the expression for  $E$ , insignificant at low temperatures, shows its importance in the neighbourhood of the critical point by pulling the curve down to the zero level.

It may be noticed in passing that the temperature variation of the free and total molecular surface energies, as usually defined, has been investigated along lines similar to those indicated<sup>2</sup> and it has been shown that the total molecular surface energy is not, as commonly assumed, independent of the temperature, but varies therewith according to a rather complicated law. For low values of the temperature, the variation is slight, the energy rising to a slight but definite maximum at a reduced temperature of 0.79, hereafter falling rapidly to zero at the critical point.

The quantities  $\gamma_0$  and  $e_0$  are functions of the critical constants; van der Waals has given reasons<sup>3</sup> for putting

$$\gamma_0 = K\theta_c V_c^{-1}$$

where  $K$  is a universal constant and  $V_c$  is the critical *molecular* volume. Having determined values for  $\gamma_0$  for a number of substances for which the critical data are available, we assumed that

$$\gamma_0 = K\theta_c^a V_c^b$$

and determined the constants  $K$ ,  $a$  and  $b$  by the use of the method of least squares. We find that

$$\gamma_0 = 3.12 \cdot \theta_c \cdot V_c^{-0.55}$$

and the fit of this equation is tested later.

<sup>2</sup> Ferguson and Miller, *Proc. Physic. Soc.*, 1934, **46**, 140.

<sup>3</sup> Van der Waals, *Z. physik. Chem.*, 1894, **13**, 716.

Similarly putting

$$e_0 = K_1 \theta_c^f \cdot V_c^g$$

we find, using the values of  $e_0$  already deduced that

$$e_0 = 0.811 \theta_c V_c^{0.176}$$

But the parachor  $P$  is a simple function of  $e_0$  and  $\gamma_0$  and if we assume  $p = 4$  we find that

$$e_0 = \gamma_0^{\frac{1}{2}} \cdot P^{\frac{1}{2}}$$

and therefore, on substituting the values of  $e_0$  and  $\gamma_0$  we have

$$P = A \cdot \theta_c^{\frac{1}{2}} V_c^{\frac{1}{2}}$$

The fundamental table in this paper is Table I. Here are tabulated values of  $\gamma_0$ ,  $n$ ,  $p$ , and  $e_0$  for a group of substances representing very varied types of organic liquid. To obtain data for these calculations we have searched the literature fairly thoroughly and critically, and our authorities are indicated in the second column.

We have not thought it worth while to tabulate the values of  $(n - 2n/3p)$  and  $(n - 1 - \frac{2n}{3p})$  as these can be obtained at once from the table.

Given tables of critical data and of densities, it is possible from this table to calculate at any temperature trustworthy values of surface tension ( $\gamma$ ), total surface energy ( $\lambda$ ) and free and total molecular surface energies. It will be seen from the table that  $p$  deviates very sensibly

from 4 for a number of substances, and Table II. shows how the definition of the parachor as  $(MC^{1/2})$  alters the values of  $P$  as compared with the value given by the fourth power law.

We have seen that it is possible to put empirically

$$e_0 = 0.811 \theta_c V_c^{0.176} \text{ and } \gamma_0 = 3.12 \theta_c V_c^{-0.55}$$

Table III. shows how closely these results are followed. In these columns  $e_0$  (obsd.) and  $\gamma_0$  (obsd.) refer to values calculated as described directly from the surface tension data;  $e_0$  (calcd.) and  $\gamma_0$  (calcd.) refer to values calculated by substituting values for the critical constants in the equations just given.

Table IV. similarly shows values of the parachors of various substances calculated from the equation

TABLE III.

Diethyl ether . . .	56.72	56.21	1028	1020

$$P = A\theta_c^{\frac{1}{2}} \cdot V_c^{\frac{1}{2}}$$

In this table are listed for comparison Sugden's values of the parachor as calculated from their elementary values. It will be seen that the agreement is reasonably good. (The value of  $A$  used in these computations is 0.324).

Finally, a preliminary and tentative attempt has been made to investigate the relation between chemical constitution and the values of  $e_0$  and  $\gamma_0$ . The usual procedure has been followed, a mean value for  $\text{CH}_2$  being obtained, and values for carbon and hydrogen deduced by means of the paraffins. Values for other elements are then obtained, and the usual allowances may be made for the nature of the oxygen or other linking.

Such calculations suffer from paucity of data, and it is much to be hoped that anyone making a surface tension determination will obtain values over a wide range of temperature. It is only thus possible to obtain complete information concerning the surface energy of the liquid and its surface constants.

From a comparison of the values of  $e_0$  for different members of various homologous com-

Diethyl ether . . .	209.7	210.2
Acetone . . .	169.9	160.2

pounds we find a mean value for  $\text{CH}_2$  of 106 units. Combining this with the values for the paraffins we find in the usual way that the value for hydrogen is 262 units and for carbon *minus* 418 units. For oxygen in the ether group the value is 74.5 units.

With these figures it is possible to make a rough comparison of the calculated and observed values of  $\epsilon_0$ . These are shown in Table V.

These figures are, however, merely a preliminary contribution; the present paper is chiefly concerned with the calculation and listing of the more important surface tension constants. We hope, in a later paper, to discuss the effects of composition and constitution in some detail.

*Note by A. F.*

The work has been made possible by the assistance of a grant from the Department of Scientific and Industrial Research, and I desire to offer my thanks to the Advisory Council of the Department for their assistance, and to Prof. H. R. Robinson who has given every facility for the prosecution of the investigation.

## REVIEWS OF BOOKS.

**Die Allotropie der chemischen Elemente und die Ergebnisse der Röntgenographie.** By M. C. NEUBURGER. Stuttgart: Ferdinand Enke, 1936. Pp. 106, with 32 illustrations. Price R.M. 9.30.

The author has performed a valuable service in bringing together the results of scattered observations dealing with the general subject of allotropy. Most of the book is composed of a systematic review of the elements, reinforced with brief discussions of the influence of impurities, atomic properties, and the mechanism of transformations. Within limits, this is all that could be expected, and the monograph does not set out apparently to be the last word on this aspect of energetics. Nevertheless, one or two comments may be offered.

To take details first (since they concern the systematic part of the book), one would hesitate to subscribe to the view that bismuth shows only one form. It is hard to say exactly, but magnetic work of the greatest delicacy seems to imply that this substance passes through a number of allotropic changes packed very closely together (on a temperature scale) just beneath the melting-point. Again, it may be true that iodine is not allotropic: it is very difficult to credit it; not because definite proof of two forms can be advanced, but for theoretical reasons.

Allotropy is a subtle and fascinating study, and those who indulge in it need a special flair, which enables them intuitively to track down its existence; convictions exist that something is allotropic, and years may go by in establishing it. Furthermore, the phenomenon may be substructural, and X-ray analysis may therefore not be conclusive. These thoughts, however, do not detract from the value of Dr. Neuburger's book; we shall turn to it for help very often.

F. I. G. R.

**Theory of Machines.** By LOUIS TOFT, M.Sc., and A. J. T. KERSEY (third edition). London: Sir Isaac Pitman & Sons, Ltd. 12s. 6d.

This is a new edition of the well-known text-book for engineering students. The opportunity has been taken to add some notes on boundary lubrication to Chapter VII. dealing with Friction and the Theory of Lubrication, and also to explain the tabulation method of treating problems on epicyclic trains—a method which many students have found helpful. The chapter on Oscillations and the Whirling of Shafts has been extended to deal with modern developments in high speed internal combustion engines.

**Chromium Plating: with Special Reference to Its Use in the Automobile Industry.** By O. BAUER, H. ARNDT, and W. KRAUSE. Translated from the German by E. W. PARKER. London: Edward Arnold & Co., 1935. Pp. vi + 266. Price 25s.

In view of the great importance of chromium plating to the automobile industry, the authors of this book, O. Bauer, H. Arndt and W. Krause, working under the auspices of the German State Bureau for Testing of Materials, carried out an extensive investigation on the properties of actual specimens of plated automobile parts. The principal aim of this work was to obtain data of a reliable and unbiased character which could be placed at the disposal of the industries concerned, with the object of raising the general standard of commercial chromium plating. The results were published as an official German report, and a translation of this forms the basis of the present book. The text has been modified by the introduction of additional material which provides a fuller survey of English, American and Continental practice than was given in the original report, and the bibliography has been greatly extended in this connection and also brought up to date. In addition a short introductory chapter relating the properties of nickel and chromium deposits to electroplating practice has been written by A. W. Hotherhall.

The title of the book is somewhat misleading: not more than a page or two is actually devoted to the practice of chromium plating, most of the subject-matter dealing with the testing of chromium-plated articles. The chief headings under which the tests are described are: surface quality; adhesion; hardness and wear-resistance; resistance to high temperatures and reversal of temperature; porosity; and corrosion resistance. It is certain that the investigations have been carried out with marked thoroughness, and the large number of tables, diagrams and photographs aid materially in making the results clear to the reader. A valuable and

concise summary of the conclusions to be drawn from the work are given in the final chapter. The bibliography, which contains nearly 600 references, is mainly concerned with papers and books published between 1920 and June 1935; patent literature as such is not included, but references are given to publications in which patent claims are considered.

The translator and publishers have done their work well: the price of the book is high for its size, but this is undoubtedly due to the expense involved in the high-class reproduction of some 190 half-tone plates. The book can be recommended to all organisations concerned with chromium plating or with the use of chromium-plated materials.

S. G.

**Electron Emission and Adsorption Phenomena.** By J. H. DE BOER; Translated from the manuscript by MRS. H. E. TEVES-ACLY. Cambridge University Press, 1935. Pp. xi + 398. 21s. net.

The object of this book is to co-ordinate for the first time what may be called the physics and the chemistry of surfaces. It gives a connected story of electron emission from metals and the adsorption of atoms on their surfaces. After two excellent introductory chapters on thermionic emission and the nature of adsorption forces a detailed account is given of the influence of adsorbed layers on the emissive properties of metals, particularly of caesium and similar atoms on tungsten. After a statement of the facts observed by Langmuir, Becker and other workers, the author shows that it is possible to construct a satisfactory picture of the nature of adsorbed layers on metallic surfaces from the phenomena of thermionic emission. He then examines the extent to which this picture is in accord with the results obtained in photoelectric emission and shows that the main facts can be readily explained. The selective photo effect is shown to be the result of the absorption of light by adsorbed atoms and hence it is useful as an indicator of the presence of neutral atoms as well as ions on a surface.

In the second part of the book the properties of alkali metal atoms adsorbed *within* dielectrics are discussed and their photoelectric properties are compared with those adsorbed on surfaces. The absorption of light of suitable wave-length can produce photoionisation but, since the electrons thus ejected must have energies which lie between definite limits determined by the lattice structure of the dielectric, the absorption spectrum has certain characteristic differences from that of the same atoms adsorbed on the exterior surface. The movement of the ejected electrons within the solid produces that interesting set of phenomena described as photoelectric conductivity, an account of which the book provides.

This is a particularly interesting book written from a novel point of view. The style is simple and easy, being non-mathematical and descriptive, and the English, though a translation, is surprisingly good. It is marred only by one or two unusual descriptive terms, such as "ionisation tension" instead of the usual English "ionisation potential" (p. 143). There is a free use of potential curves to represent visually energy relations of all kinds, which greatly adds to the interest and enjoyment of the reader.

J. E. L.-J.

**The Principles of Quantum Mechanics.** By P. A. M. DIRAC. Second Edition. Oxford: Clarendon Press, 1935. Pp. xi + 300. Price 17s. 6d.

This is a revised edition of a book which is generally accepted as the most logical and authoritative exposition of the laws of quantum mechanics yet produced. The presentation has been changed so as to reduce the abstract character of the first edition, and is likely to appeal to a wider circle of readers.

The main alteration centres round the use of the word "state." A satisfactory system of mechanics must provide a method of dealing with the relations and laws of nature governing the state of affairs in an atomic system at one instant of time and must also show the connection between the state of affairs at one instant of time with those at other instants of time. The new use of the word "state" is to make it refer to the condition of the dynamical system at one instant of time, and so the "state" of a dynamical system may be regarded as continually changing under the influence of the equations of motion. This new definition is non-relativistic, as it refers to conditions in a three-dimensional section of space-time belonging to one time-instant. The author expresses the view that this concept of "state" facilitates a clear exposition of the subject and induces the belief that probably the fundamental ideas of the present quantum mechanics need revision at just this point.

Another change from the first edition is the addition of a chapter on the quantum theory of the electromagnetic field, but the present formulation of this theory is very complicated and, as the author points out, it has not yet produced any results which cannot be obtained by more elementary methods. A satisfactory theory of the radiation field and its interaction with matter has not yet been produced.

This edition, like the first, is a model of clear and logical exposition. It is expressed in simple language even when the ideas involved are complex. It is a scholarly book and can be thoroughly recommended to all who seek a clear formulation of the laws of quantum mechanics as they stand at present.

J. E. L.-J.

**Thorpe's Dictionary of Applied Chemistry.** Supplement. Vol. III., Glossary and Index. By J. F. THORPE and M. A. WHITELEY. (London: Longmans, Green & Co. Pp. 166 and vii. 21s. net.)

This concludes the labour of bringing the last edition of Thorpe up-to-date. Those who have used Vols. I.-VII. have well realised the utility of the Index in Vol. VII. An index to the two supplementary volumes was therefore keenly awaited. Needless to say, it has been well done. This volume also includes a glossary of terms, which will often be helpful.

WILLIAM RINTOUL  
(President of the Faraday Society, 1934-6),  
Died 25th August, 1936.

# WILLIAM RINTOUL

*President of the Faraday Society, 1934 to 1936*

---

MR. WILLIAM RINTOUL died at his home in Ardrossan on the 25th of August at the age of sixty-six. He was educated at Anderson's College, Glasgow, and received further chemical training in the laboratories of Mr. R. R. Tatlock, one of the few schools of analytical chemistry. He was for a short time an assistant and then a lecturer in chemistry to Tatlock's students. In 1891 he came to London as chemist to a paint manufacturer, but in 1894 started out on his life-work. First at Waltham Abbey with his friend Robert (now Sir Robert) Robertson, under Sir Frederic Nathan, and, after 1909, at the Ardeer factory of Nobel's Explosives Co., whither he accompanied Sir Frederic, he was concerned in the safety and efficiency of manufacture of explosives. As research manager at Ardeer he reorganised the laboratories and started new ones, as, for example, for biochemical and physical work; his policy, specially in regard to the organisation of the work of his laboratories and the documentation of these results and of relevant work published in the literature, has been the model for many other research organisations. When Nobel's joined Imperial Chemical Industries, Rintoul came to London as joint research manager of the larger organisation, and here his organising abilities found even fuller scope; his correlation of industrial and academic research will be specially remembered.

He gave generously of his time to the work of councils and committees, serving on the Councils of the Chemical Society, and of the Institute of Chemistry and on the Federal Council, the Safety in Mines

Research Board, the Chemistry Research Board (D.S.I.R.), the Research Committee of the L.M.S. Railway and the British Standards Institution. As a representative of his firm he was well-known abroad, and he often attended meetings of scientific societies in this country and on the Continent. For his work in the Great War he was made an O.B.E.

He married first Lottie Edwards, by whom he had two sons and a daughter, and, two years ago, Jess Isabel Robertson, the sister of his former colleague.

Rintoul served on the Council of the Faraday Society continuously from 1930, and in October, 1934, he became President. He took a living interest in the work of this Society and especially in the formation of the Colloid Committee, of which he was an original member. His enthusiasm for the Colloid meetings, a subject to which he was perhaps drawn from his acquaintance with gelatinised nitrocellulose, culminated in the very successful meeting on the Phenomena of Polymerisation and Condensation, which was held at his suggestion and under his presidency.

He will long be remembered by those who were privileged to attend the meetings under his presidency at the Imperial College in April, 1935, and in Cambridge in September, 1935, where his tact in conducting the business and the charm of his personality, evinced both during the meetings and informally in his room, as host, made those meetings an outstanding success. Shortly after the Cambridge meeting news was received of his serious illness, but, though he was unable to preside at the spring meeting of 1936, he looked forward with special joy to welcoming the Society in the autumn to his home country; his absence from the Edinburgh meeting gave added poignancy to the Society's loss.

It is given to few men to have made so many real friends.

# SOME NEW ULTRAVIOLET BANDS OF SO, IN EMISSION.

BY G. KORNFELD.

*Received 2nd July, 1936.*

In a previous investigation<sup>1</sup> an electrodeless discharge passing through SO<sub>2</sub> had been used to obtain the emission bands of SO. On casual observation it was then found that the spectrum obtained on the photographic plate extended to nearly 2100 Å. if the exposure was taken through the wall of the tube, whereas the spectrum taken as usual through the plane end extended only to about 2400 Å. This observation was easily explained since the absorption of SO<sub>2</sub> in this region has been found to increase again towards shorter wave-lengths<sup>2</sup> and since the discharge occurred in a ring against the wall, whereas its distance from the plane end was not much less than 1 cm.

From more than one point of view it seemed interesting to investigate this new part of the emission spectrum. First of all it was important to make sure that the emission band system of SO did not extend farther to the ultra-violet than with the last band previously observed.<sup>3</sup> Since predissociation has been assumed in this region<sup>4</sup> on the basis of the experimental result, and since the energy of dissociation of SO has been calculated on this assumption, it seemed worth while to find out whether this result was established beyond doubt, and whether, even if the bands should be found to continue to shorter wave-lengths, there would be a break at least in the critical region. On the other hand, if the bands should be found not to belong to this system of SO or perhaps not to SO at all, it seemed important to ascertain to which of the partaking ions or molecules they could be ascribed.

## Experimental Procedure.

The sulphur dioxide used in this investigation was first carefully prepared by a method already mentioned<sup>5</sup> but, however carefully employed, the CO bands were always present in the ultra-violet region. A much simpler method proved, however, to be successful: the quartz discharge tube was connected at one end to a flask containing liquid SO<sub>2</sub>, and at the other end—through a large tube filled with KOH—to an ordinary Hyvac pump. By regulating the taps on both sides a suitable pressure for the discharge could easily be maintained during the exposure. With this method no CO bands were visible on the plate.

The electrodeless discharge was maintained by an oscillator with a powerful valve (used at 125 milli amps.) connected to a generator yielding

<sup>1</sup> G. Kornfeld and M. McCaig, *Nature*, 1935, 135, 185.

<sup>2</sup> G. Kornfeld and E. Weegmann, *Z. Elektroch.*, 1930, 96, 93.

<sup>3</sup> V. Henri and F. Wolff, *J. Physique et Radium*, 1929, VI, 10, 81.

<sup>4</sup> E. V. Martin, *Physic. Rev.*, 1932, 41, 167.

<sup>5</sup> G. Kornfeld and M. McCaig, *Trans. Farad. Soc.*, 1934, 30, 991.

up to 3000 volts. The electrodes, separated by about 7 mm. from one another, were adjusted round the tube ( $d = 25$  mm.).

The colour of the discharge depended on the pressure; at low pressures it was a vivid violet, changing towards blue with increasing pressure, until the discharge showed a strong blue colour. At still higher pressures the discharge could not be maintained. The numerous bands in the region below 2400 Å. could not be found in the spectrograms of the violet discharge, but only of the blue discharge. The investigation of the new bands was therefore carried out with the discharge of blue colour; this blue light was continuous in the visible region and there was also a very strong continuous spectrum in the ultra-violet region, diminishing gradually to about 2300 Å. The long exposures needed for the bands below 2400 Å. made the continuous spectrum rather strong in the region of longer wavelengths. During the exposure the pressure had to be carefully regulated by adding a small amount of  $\text{SO}_2$ , whenever the colour began slightly to change, owing to diminishing pressure of  $\text{SO}_2$ , arising from its decomposition, as was clearly demonstrated by the large amount of sulphur deposited on the walls of the tube (outside the region of the discharge).

The spectrograms were taken with a medium size quartz spectrograph (Hilger E2) with a dispersion of 8 Å. per mm. at 2400 Å.

### The Spectrum of the Discharge.

Down to about 2440 Å. the continuous spectrum was very strong on the photographic plate and accordingly there the bands were only faintly visible; in the region of shorter wave-lengths, however, which was the object of this investigation, the bands could be seen clearly enough to be measured.

Fig. 1 is an enlarged negative print (the emission bands and lines are seen to be dark against the white background) of this band spectrum together with the line spectrum of an iron arc. The numerous bands, varying somewhat in intensity, are slightly degraded to the red; in most of them there is no structure, only in a few can some faint traces of structure be detected.

In the region between 2180 and 2150 Å. some bands are just visible, though not sufficiently clearly to be registered. But most of the bands could be registered and were measured by comparing them with the lines of the iron arc and the copper arc, the latter being used for the farther end of the ultra-violet region.

### The Analysis of the Spectrum.

In Table I. all the band heads of the region below 2443 Å. are given in Ångström units. Fourteen of them, indicated by brackets, coincide within 1 Å. with known absorption bands\* of  $\text{SO}_2$ ; considering, however, that

FIG. 1.

*To face page 1488.*

the discharge occurred close to the wall, practically no absorption should be expected to be visible on the plate, especially in the region about 2300 Å., where the intensity of absorption is comparatively small.<sup>1</sup> On the other hand, an accidental coincidence of so many bands seems rather improbable, unless they belong to the same system, which means that in this case they should belong to  $\text{SO}_2$  in emission. In the positive column of a discharge passing through  $\text{SO}_2$ , Chow<sup>2</sup> has found numerous new emission bands between 2600 and 2040 Å. of which twenty-eight coincide with bands given in Table I. (some coinciding also with the absorption bands) and are there italicised. Sixteen of these twenty-eight (asterisked) have been identified by Chow as belonging to the emission of  $\text{SO}_2$ , and some of them can be found also amongst W. Lotmar's<sup>3</sup> fluorescence bands; with which sixteen further bands of Table I. (marked +) have been found to coincide, so that only ten bands are left which were not known. An attempt to arrange these ten (as well as the others) in accordance with the band system of SO proved unsuccessful, and thus the possibility of SO emission bands existing beyond the assumed limit of predissociation has been negatived. It seemed reasonable to try whether these bands could not be ascribed, along with the others, to the emission band system of  $\text{SO}_2$ .

The frequencies of the normal electronic state of  $\text{SO}_2$ ,  $\nu_1$ ,  $\nu_2$ , and  $\nu_3$ , have lately been determined by various authors. Lotmar, investigating the fluorescence spectrum of  $\text{SO}_2$ , found the values 1150, 520 and 1370  $\text{cm}^{-1}$  (in his numbering  $\nu_1$ ,  $\nu_2$ , and  $\nu_3$ ), well agreeing with the Raman frequencies.<sup>4</sup> These values, especially the first two, were confirmed by Chow and by H. D. Smyth<sup>5</sup> and quite recently by J. H. Clements<sup>10</sup> in his investigation of the absorption spectrum between 3300 and 2600 Å. This spectrum belongs to another upper level than the absorption spectrum in the farther ultra-violet region, but both systems share the same initial level; the absorption spectrum in the farther ultra-violet region<sup>11</sup> has been found to share both electronic levels with the fluorescence bands of Lotmar and with the emission bands of Chow. For the upper level Lotmar found the progression 390  $\text{cm}^{-1}$  or a multiple, Chow found 375  $\text{cm}^{-1}$  or a multiple for the absorption bands; in his scheme for the emission bands he assumed three different progressions, one of which he took to be 750-770  $\text{cm}^{-1}$ , whereas the others were still uncertain.

The wave-numbers of the bands of Table I. proceed along the three progressions, 380, 500 and 1140  $\text{cm}^{-1}$ ; from the above-mentioned investigations the first is likely to belong to the upper level, while the other two coincide with two frequencies found for the ground level; there is no evidence for a progression along the third fundamental frequency, 1370  $\text{cm}^{-1}$ . The bands have accordingly been arranged in a scheme represented by Tables II., III. and IV. Assuming that  $\nu_1'' = 1140 \text{ cm}^{-1}$ ,  $\nu_2'' = 500 \text{ cm}^{-1}$  and, tentatively, that 380  $\text{cm}^{-1}$  could be ascribed to  $\nu_3'$ , each table represents two progressions along  $\nu_1'$  and  $\nu_2''$  respectively, the mean values for  $\nu_3'$  being: 377, 403, 381, 381, 386, 384 and for  $\nu_2''$ : 500, 499, 506; the mean differences from one table to another are 1143 and 1140  $\text{cm}^{-1}$ , in good agreement with a progression along  $\nu_1''$ . The bands coinciding with absorption bands are again marked by brackets; bands used in more than one table are italicised; in a few cases the wave-numbers have been corrected to fit in better with the scheme, the difference between both values being about 20  $\text{cm}^{-1}$  and never amounting to more than 30  $\text{cm}^{-1}$ ; where this has been done the original values are indicated below the new ones.

The arrangement seems to be satisfactory although, considering that  $3\nu_1' \sim \nu_1''$ , it cannot be taken as final: there are other possibilities; if

more coincidences be assumed to occur, Tables III. and IV. would contain many additional bands. Even accepting this, however, no conclusive evidence can be given for the absolute numbering of the progressions;  $m$  and  $n$ ,  $a$  and  $b$  are not defined, even if it is assumed that  $\nu_1$  in both levels is not excited. An indication, however, might be found in Table V. which

TABLE V.

$\begin{array}{c} \nearrow v' = b. y. 0 \\ \searrow v'' = a. x. 0 \end{array}$	$y=n$	$y=n+1$	$y=n+2$	$y=n+3$	$y=n+4$	$y=n+5$	$y=n+6$	$y=n+7$	$y=n+8$

contains the rest of the bands—with a mean difference of  $1200 \text{ cm}^{-1}$  from those in Table II. Now Clements found  $1200 \text{ cm}^{-1}$  to be the difference between the first and the second vibrational level belonging to  $\nu_1''$ , so that  $a$  should be equal to unity. Supposing that  $m = 0$  and  $n = 0$ , the wave-number for the transition between the upper level with  $v' = b. 0. 0$  and the ground level with  $v'' = 0. 0. 0$  should be  $46,050 \text{ cm}^{-1}$ . For  $\nu_1$  Chow found  $45,757 \text{ cm}^{-1}$ : the difference of  $300 \text{ cm}^{-1}$  should then be accounted for by  $\nu_1'$ .

These latter suggestions are, however, only tentatively made, since the level indicated by Table V. contains only a few scattered bands; moreover, the difference of  $1200 \text{ cm}^{-1}$  might instead belong to the upper state, and then  $a$  could not be determined at all.

Apart from these conclusions concerning the numbering of the vibrational levels the scheme works satisfactorily since it contains all the bands. The combined levels of  $\nu_1'$  and  $\nu_1''$  seem to be characteristic of this special scheme; in Chow's paper the levels  $\alpha_1$  and  $\alpha_2$  are given, corresponding to  $1\nu_1' + 1\nu_1''$  and  $1\nu_1' + 2\nu_1''$  respectively, but no levels are mentioned which would correspond to the higher numbers combined in this investigation. Such levels, however, could be derived from the progressions of Lotmar's fluorescence bands; the small amount of coupling, too, between  $\nu_1'$  and  $\nu_1''$  ( $\nu_1'$  and  $\nu_1''$  in Lotmar's numbering) is in good agreement with Lotmar's experience. It seems, however, that the exclusive preference of these levels must be ascribed to the special conditions of the high frequency discharge. The absence of any transitions including a change in  $\nu_2$  seems to be another characteristic feature of this discharge.

### Summary.

An electrodeless discharge of a strong blue colour passed through  $\text{SO}_2$  along the walls of a quartz tube through which a spectrogram was taken. Between  $2443$  and  $2120 \text{ \AA}$ . the heads of fifty-nine bands were measured, of which forty-nine coincided with bands known to belong to  $\text{SO}_2$ . Neither these nor the remaining ten could be added to the known system of  $\text{SO}$  bands, so that there is no evidence of any emission bands beyond its established limit of predissociation. All the bands are consistent with the

known band system of  $\text{SO}_2$  in emission, and a special scheme has been suggested where the vibrational levels of the ground state are combined of higher numbers of  $\nu_1$  and  $\nu_2$ .

The experimental part of this work was done at the Astrophysics Department of the Imperial College in London. The author desires to thank Professor G. P. Thomson and Professor H. Dingle for their hospitality. She is specially indebted to Dr. R. Pearse for his helpful and constructive criticism then and afterwards. Many thanks are further due to Hofrat Professor Mache of the *Physikalisches Institut der Technischen Hochschule* in Vienna for kindly allowing the use of his comparator. Finally, the author wishes to thank the American Association of University Women for the International Fellowship of this academic year which enabled her to carry out this investigation.

## NOTE ON THE MECHANISM OF CATALYTIC INTERCHANGE OF HYDROGEN WITH WATER AND ALCOHOL.

BY JURO HORIUTI AND GO OKAMOTO.

*Received 30th July, 1936.*

The authors have observed previously<sup>1</sup> that a nickel sheet operates as a reversible hydrogen electrode at 50°C. The main points of their observation with this hydrogen electrode are as follows:

(1) The rate of interchange of hydrogen with the solution at varying electrode potential over a range of a few tenths of a volt, remains constant within a factor 1 to 2.

(2) When the hydrogen electrode in the reversible state is positively polarised, the initial current decreases gradually, tending to a definite value. When, further, the polarisation of the electrode in the steady state is decreased, the small initial current increases gradually, tending again to a definite value. This final steady current, can be reproduced by arranging the partial pressure of hydrogen and the polarisation.

Assuming that these processes<sup>2</sup> take place in two steps,

it was concluded that the rate determining step is the first one, i.e. atomisation of hydrogen molecule on the metal. The second step is the ionisation of atoms. The argument which leads to this conclusion will be briefly reproduced here.

Electrode potential changes only the rate of ionisation. Assuming that the bond  $\text{Me} - \text{H}$  is homopolar, the first step is not appreciably influenced by the electrode potential. If it were polar (e.g.  $\text{Me}^- - \text{H}^+$ ) either atomisation or ionisation is the rate-determining step. If atomisation, the second experimental fact can always be explained while the small variation

<sup>1</sup> Horiuti and Okamoto, *Sc. Pap. I.P.C.R.*, 1936, **28**, 231

<sup>2</sup> Another mechanism was suggested for the electrode process on poor recombination catalysts, such as Hg and Sn.

of interchange reaction rate might partly be attributed to the effect of the influence of the electrostatic field. If ionisation, the concentration of  $\text{Me}^- - \text{H}^+$  should increase initially on raising the electrode potential, since the energy of  $\text{Me}^- - \text{H}^+$  is lowered, and the current should increase initially; this is contrary to experiment. It is highly improbable that the second step is the rate determining one and the opposite polarity  $\text{Me}^+ - \text{H}^-$  since the electron affinities of nickel and hydrogen are 4.9 and 0.7 volts respectively. It follows that the observed result (1) can only be explained by adopting atomisation as the rate determining step.

Further if  $\text{Me} - \text{H}$  were in incipient equilibrium with  $\text{Me} + \frac{1}{2}\text{H}_2$ , the concentration of  $\text{Me} - \text{H}$  should be constant, independent of polarisation. The steady current must be obtained immediately after polarisation. Alternatively, the concentration of  $\text{Me} - \text{H}$  should increase or decrease with the rate of ionisation until the new preliminary equilibrium at the given polarisation is set up. It follows that the current should initially decrease or increase according as the positive polarisation is raised or lowered. The two experimental facts can be thus only accounted for by assuming the atomisation as the rate determining step.

Following the program announced in the previous paper<sup>1</sup> the writers have calculated the theoretically absolute values of anodic and cathodic currents, interchange reaction rates and isotopic separation factor; they are in fair agreement with the experimental results, the concluded rate determining step and the homopolar bond  $\text{Ni} - \text{H}$  being assumed as the basis of the calculation.<sup>3</sup> Moreover Tafel's empirical relation as to the overvoltage could be derived.

The question as to the rate determining step for the electrode process seems to have been thus settled, so far at least as nickel metal is concerned.

The authors do not feel fully justified, however, in extending the conclusion to the case of platinum. In the work of Hirota and one of us which will soon be published, it is shown that the interchange rate of hydrogen with water in the presence of platinum is  $10^6$  times greater than in the case of nickel for the same apparent area of catalyst. This difference corresponds to the activation energy of 7 K cal., if the temperature independent factor remains approximately the same in both cases. In another work of Hirota, the activation energy of the interchange reaction on nickel was determined as 13 K cal. The activation energy with platinum should accordingly be 6 K cal., instead of 10.2 K cal. as observed by Polanyi in conjunction with one of us.<sup>4</sup> This is, of course, a very crude estimate, but some doubt persists whether the rate determining step is really the atomisation in the case of platinum too. Further complication is to be expected, if the rates of both steps are comparable for, according to the theory of Volmer<sup>5</sup> and Frumkin<sup>6</sup> as extended by Polanyi in conjunction with one of us,<sup>7</sup> the height of the potential barrier for ionisation varies with the electrode potential and, consequently, with the nature and acidity of the solution. It is, therefore, conceivable in this case that either of the two steps alternately governs the rate.

More recently Eley and Polanyi have conducted extensive experiments on the *para-ortho* conversion of hydrogen together with that on the interchange rate of hydrogen with water and alcohol in the presence

<sup>7</sup> Horiuti and Polanyi, *Acta Physicochim.*, U.S.S.R., 1935, 2, 505.

of platinum black.<sup>8</sup> They found (1) the first order rate of the spin conversion  $k_p$  is 2 to 3 times greater than that for the isotopic replacement  $k_d$  in most of their cases, although approximately equal in some cases. (2) Both the rates are faster in acid solution than in alkaline. The difference is most pronounced in the case of alcohol: addition of alkali reduces the rate by a factor 4.

Eley and Polanyi conclude provisionally from these results that the rate determining step is the atomisation of hydrogen molecules in accordance with our previous conclusion for nickel.<sup>1</sup> In order to account for the second result Eley and Polanyi assume that the rate of atomisation is influenced by the electrode potential, the product of splitting being strongly polar.

We will now consider here some possible alternatives which also fit their experimental results.

Admitting the suggested polarity of the product of atomisation, the observed parallelism between  $k_p$  and  $k_d$  would equally follow, whether it is atomisation or the ionisation which governs the rate, since the rate of atomisation would then vary, along with the ionisation, with variation in the electrode potential. Atomisation as the rate determining step is no more conclusive. If the ionisation is slower, however,  $k_p/k_d$  must be greater than in the opposite case. By poisoning the catalyst, *i.e.* by reducing the rate of the atomisation  $k_p/k_d$  must be lowered, as is seen from their results.

Assuming on the other hand the homopolar bond  $Pt-H$ , it is possible that it is the atomisation which governs the rate. It remains now to explain the observed effect of acidity. It is possible that this rather small effect is due to poisoning; it is well known that the poisoned platinum catalyst may be reactivated by oxygen. Eley and Polanyi attribute the sudden increase of catalytic activity observed in the course of their experiment to the admission of air. In the operation of changing the solution from acidic to alkaline the catalyst must be brought in contact with air-containing liquid. Deactivation by the poison contained in alkali and subsequent reactivation by air might possibly be the cause of the observed "reversibility." To clear the matter up, it is desirable to perform experiments with solutions previously depoisoned by keeping them for some time in contact with platinum catalyst, as has been done by Volmer and Wick.<sup>9</sup>

# THE CATALYTIC ACTION OF HYDROGEN ON THE CARBON MONOXIDE FLAME.

BY HENRY JAMES WALLS.

*Received 6th August, 1936.*

The mechanism of the reactions occurring in the carbon monoxide flame is still far from clear. But in most of the various schemes of reaction which have been put forward, the processes, once the flame has been started, are assumed to be mainly homogeneous. The facts presented below, however, suggest that the nature of the walls has a considerable influence on the course of the reaction. Garner and his co-workers have established<sup>1, 2, 3</sup> that when the infra-red radiation emitted from the explosion of a carbon monoxide-oxygen mixture containing hydrogen is plotted against the initial pressure of the gas, a "step" or discontinuity in the curve occurs, indicating a sudden change at a given pressure in the amount of radiation emitted. The pressure at which this step occurs is connected with the partial pressure of hydrogen in the mixture by the equation<sup>4</sup>

$$(p_s \times p_{H_2} + 0.018p_s)/3.28 = 1 \quad . \quad . \quad (1)$$

where  $p_s$  is the pressure at the step, and  $p_{H_2}$  is the pressure of hydrogen for which the step occurs at  $p_s$ .

It is noteworthy that  $p_s$  is hardly affected by the nature of the material composing the vessel in which the combustion takes place, and that it is increased by the addition of carbon dioxide, chlorine, or bromine to the explosive mixture,<sup>3, 4</sup> while it is unaffected by a 33 per cent. increase in the concentrations of either carbon monoxide or oxygen.<sup>2</sup>

Garner and Pollard<sup>4</sup> have discussed two possible explanations for the existence of this step, *viz.*,

(a) that the step represents a lower limit for the propagation of a hydrogen flame in a carbon monoxide-oxygen mixture, or

(b) that the step is the pressure at which two mechanisms of combustion (presumably involving, and not involving hydrogen, respectively; the latter case may be either an oxygen atom or a thermal chain; see *e.g.*, Alyea<sup>5</sup>) produce flames travelling at equal speeds. The authors decide that (b) is the most probable explanation.

The newer theories of explosion, however, largely developed by Semenov and his school, provide us with a method for settling this question definitely. For an explosive gaseous mixture the lower limit of ignition is connected with the temperature by the equation<sup>6</sup>

$$\log p = \frac{A}{T} + B \quad . \quad . \quad . \quad (2)$$

<sup>1</sup> Garner and Hall, *J.C.S.*, 1930, 2037.

<sup>2</sup> Garner, Hall and Harvey, *J.C.S.*, 1931, 641.

<sup>3</sup> Bawn and Garner, *J.C.S.*, 1932, 129.

<sup>4</sup> Garner and Pollard, *J.C.S.*, 1935, 144.

<sup>5</sup> Alyea, *J. Amer. C.S.*, 1931, 53, 1324.

<sup>6</sup> Semenov, *Chemical Kinetics and Chain Reactions*, p. 83.

where  $A$  and  $B$  are constants. It is obvious that if hypothesis (a) is correct, *i.e.*, if the step represents a definite lower ignition limit, the step must move to lower pressures as the temperature increases; conversely, if increase of temperature raises  $p_s$ , (a) cannot be correct, and (b) is then the most probable explanation. This question was tested experimentally, and it was found that  $p_s$  rises with temperature.

### Experimental.

The apparatus was similar to that used by Garner and Roffey for measuring the radiation from gaseous explosions.<sup>7</sup> The purified, mixed and dried gases were exploded in a quartz bomb, about 30 cm. long and 2 cm. diameter, by the fusion of a small piece of very fine platinum wire. The radiation was received on a quick-acting linear thermopile, which was connected to a Downing galvanometer, and the deflections were recorded photographically on a rotating drum.

The iron gas-holder used in Garner and Roffey's apparatus was suspected of not being quite hydrogen-tight, and it was replaced by a five-litre glass bottle; when the pressure in this fell below that required in the bomb, the arrangement of the apparatus permitted the gas to be pumped into the drying-tubes by means of the large gas-burette C (*loc. cit.*,<sup>7</sup> Fig. 1).

FIG. 1.

The number of  $P_2O_5$  tubes was reduced from five to three, and a liquid-air trap was inserted between them and the bomb. As no difference in the results could be detected whether the liquid-air trap was used or not, for the majority of the experiments only the three  $P_2O_5$  tubes were used for drying the gas. The  $P_2O_5$  had been redistilled in a current of oxygen to remove lower oxides of phosphorus.

The quartz bomb was enclosed in an electric furnace capable of giving any temperature up to 600° C. (*i.e.*, the approximate ignition temperature at the pressures used of the mixture  $2CO + O_2$ ). The bomb was held in position in the furnace by means of two stainless steel rings connected by a spacing-rod about 10 cm. shorter than the bomb, an arrangement which allowed the bomb to be removed and replaced easily. The temperature inside the furnace, which was measured by means of a platinum-iridium thermocouple and a Cambridge Instrument Co. calibrated galvanometer, was constant along the length of the furnace to within 2° C.

A cylindrical copper vessel, through which water could be passed, about 30 cm. diameter and 3 cm. long, was mounted between the furnace and the thermopile to absorb as much as possible of the heat from the furnace; there was a central aperture of about 8 mm. diameter for the passage of the radiation from the bomb. Even with this arrangement, the

<sup>7</sup> Garner and Roffey, *J.C.S.*, 1929, 1123.

radiation from the hot furnace produced a potential in the thermopile greater than the apparatus could record, and much greater than that produced by the radiation from an explosion. This was overcome by the application, by means of an accumulator and a resistance-box, of a counter-potential across the thermopile such that the zero position of the light on the recording drum was as nearly as possible that of the undeflected galvanometer. This meant that the potential applied to the galvanometer was zero before explosion, and hence that the deflections were proportional to the amount of radiation, as with the cold gas.

The first experiments were done with a new quartz bomb, but after all the preliminary adjustments had been made, a trivial matter of convenience decided that the first series of measurements should be made at a high temperature ( $190^{\circ}$  C.). There seemed to be no *a priori* reason for the temperatures at which the measurements were made following any particular order, and it was hence very surprising to find that after the series at  $190^{\circ}$  had been done the normal "cold" pressure-radiation curves could no longer be obtained. Washing out the bomb with dilute hydrofluoric acid to remove the surface layers did not restore the conditions to normal. A fresh start was therefore made, using a different bomb. This bomb was one which had been used by Dr. Pollard for gases containing nitrogen peroxide, chlorine, bromine, and iodine, and had given satisfactory curves throughout: it had not previously been heated above room temperature. A series of seven runs was then made with the bomb, starting and ending with two at room temperature and including three at three different elevated temperatures each "sandwiched" in between two at room temperature, *i.e.*, the temperatures for the seven runs were, in order,  $24^{\circ}$ ,  $70^{\circ}$ ,  $22^{\circ}$ ,  $109^{\circ}$ ,  $24.5^{\circ}$ ,  $174.5^{\circ}$ ,  $24^{\circ}$ .

The results of these experiments are shown in the Fig. Only the curves for the first five series are shown, as no further new features appear in the last two. In every case a mixture containing 0.309 per cent. of hydrogen was used. In drawing the curves, the measured radiation is corrected to that for an equal mass of radiating gas in each case, *i.e.*, it is corrected to a gas temperature of  $25^{\circ}$ , and to 100 per cent. combustion. A correction was also applied for small variations (of the order of 0.5 per cent.) in the sensitivity of the galvanometer.

### Discussion.

Curve 1 is the original curve at room temperature, and is quite normal. The step occurs at 29.4 cm.; 0.309 per cent. of hydrogen corresponds to a partial pressure of 0.091 cm. Substituting 29.4 for  $p_0$  in equation (1), we get a value of 0.094 cm. for the partial pressure of hydrogen.

The effect of raising the temperature of the gas is to increase the pressure at which the step occurs (curves 2 and 4). This proves that of the two hypotheses proposed to account for the step, that of its being a lower ignition limit cannot be correct, so that the only apparent possible alternative explanation, that it is a pressure at which the two mechanisms are equally rapid, is almost certainly the true one.

This increase in  $p_0$  on heating the explosive mixture is precisely the effect which a reduction in the pressure of hydrogen would produce. However, the hypothesis of a more rapid removal of hydrogen by the heated walls can hardly be reconciled with the finding of Garner, Hall, and Harvey,<sup>2</sup> that  $p_0$  is unaffected by changes in the diameter of the bomb, which seems to show that a wall effect is not one of the factors determining  $p_0$ . One possible explanation of these apparently conflicting facts is discussed below; another is that the temperature coefficient of

the mechanism operating below the step (mechanism I.) is greater than that of the mechanism operating above the step (mechanism II.). As suggested above, mechanism I. is probably either an oxygen atom chain or a thermal chain, while II. is almost certainly a hydrogen atom chain. Kistiakowsky and Jackson have found that in the case of the photochemical oxidation of carbon monoxide, the rate is independent of temperature in the dry mixture—*i.e.*, the temperature coefficient is zero where hydrogen atom chains cannot occur—while the reaction in the presence of water vapour has a positive temperature coefficient which increases slightly with the temperature.<sup>8, 9, 10</sup>

Apart from the effect of the temperature on  $p_s$ , however, there are some unexpected features in the results. These are:

- (1) The invariance under all conditions of the curves below the step.
- (2) The fact that heating the bomb under a high vacuum \* produces changes in the curves subsequently obtained at room temperature, the extent of the change depending roughly on the degree of the preceding heating. The step becomes more diffuse, but remains at about the same pressure and of the same order of magnitude (curves 3 and 5). At the same time, the results at the pressures above the step become erratic.
- (3) The fact that the radiation above the step increases as the temperature of the explosive mixture is raised. Thus, at 45 cm. pressure the radiation is increased by 50 per cent. on raising the temperature from 24° to 109° (curves 1 and 4). This process causes the step to disappear, and at 109° and 174.5° only rather doubtful points of inflexion remain.
- (4) The effects on the percentage combustion. (This was calculated for every explosion from the drop in pressure on re-opening after explosion

the tap between the bomb and the manometer.) The values obtained tended to rise for the explosions done at the higher temperatures, and to fall again for the explosions done at room temperatures after the bomb had been heated. Some figures for this are given in the table opposite.

In the case of three series done at elevated temperatures (2, 4, 6), there was also a noticeable tendency for the percentage combustion figures to show a large deviation from the mean in the early explosions of each series, and only to settle down to a fairly steady value after eight to ten explosions. The percentage combustion varied a little with the pressure, but not much between 25 and 45 cm., and the explosions at the different pressures were done in a random order. The figures for pressures below 25 cm. are in error by an unknown amount, since at low pressures the flame was

<sup>8</sup> Kistiakowsky, *Proc. Nat. Acad. Sci.*, 1929, **15**, 194.

<sup>9</sup> Jackson and Kistiakowsky, *J. Amer. C.S.*, 1930, 3471.

<sup>10</sup> Jackson, *J. Amer. C.S.*, 1934, 2631.

\* Before doing a series of measurements at a raised temperature, the bomb was always evacuated for at least twelve hours while the furnace was on. The final vacuum was always of the order of  $10^{-6}$  mm. or better, and the evacuation was continued till the increase in pressure over half-an-hour, with the pumps shut off, was negligible.

usually extinguished in the narrow tube leading to the tap. Also, since this tube necessarily projected from the furnace, the gas in the bomb-space was not evenly heated throughout, and although the exact temperature distribution was thus unknown, the percentage combustion at the elevated temperatures was calculated assuming a temperature discontinuity—room temperature to furnace temperature—at the tap by which the gas was admitted to the bomb. To allow, however, for a temperature gradient would tend to increase, if anything, the percentage combustion figures at the higher temperatures, and hence also the differences shown in the table.

These results show that we must distinguish the changes in the reaction occurring at a raised temperature, and those appearing after the reaction vessel has been heated. 1 and 2 show that while mechanism I. is unaffected either by the heating of the walls of the vessel or by any subsequent effects, II. is apparently affected by both to a marked degree. The only explanation for this is that the nature of the surface has been changed, even by so small a rise of temperature as  $50^{\circ}$ . If it has been rendered in some way unstable, then the step, which represents a delicate equilibrium between the two mechanisms, will cease to be a definite pressure and will become instead a region of pressure throughout which each explosion can leave the surface in a condition to favour either of the two mechanisms. It is clear that changes in the surface could lead to the partial removal of some chain carrier, favouring one mechanism at the expense of the other. Garner and Pollard<sup>4</sup> have suggested that when the flame is slowed down, *e.g.*, by the presence of chlorine or bromine, the surface, by removing the hydrogen atoms concerned in mechanism II., can affect the completeness of the combustion. A similar explanation could be applied to the results obtained on and after heating, were it not for the objection which arises above, that  $p_c$  is unaffected by changes in the diameter of the bomb, indicating that the occurrence of one combustion mechanism rather than the other is not determined by the walls directly. This difficulty vanishes if we assume, firstly, that the walls are normally in such a state (possibly covered with a monomolecular layer of gas) that they cannot, during the rapid passage of a normal flame, adsorb sufficient hydrogen atoms or other chain carriers to affect appreciably the course of the reaction; and secondly, that this condition is removed by heating. This, if true, would provide also an alternative explanation to the one offered above of the positive temperature coefficient of  $p_c$ . Steiner<sup>11, 12</sup> has shown that adsorbed water poisons a glass surface for the heterogeneous recombination of hydrogen atoms; so it is possible that chemically bound water and other impurities are desorbed from the quartz on heating, thus rendering the surface more effective for the removal of hydrogen atoms. Hence the fact, noted under (4), that the percentage combustion figures tend to become less erratic with time, may be explained by a reconditioning of the surface by the adsorption of water, and possibly other substances, after a number of explosions.\* The values obtained for the radiation emitted, however, showed no tendency to lie closer to a mean curve after a number of explosions had been done; and there was no apparent connection between large deviations of percentage combustion figures on the one hand, and of amounts of radiation on the other.

\* Coslett and Garner,<sup>18</sup> investigating low pressure CO—O<sub>2</sub> flames in quartz vessels, found that the percentage combustion depended on the state of the surface.

<sup>11</sup> Steiner, *Z. physik. Chem., Bodenstein Festband*, 1931, 817.

<sup>12</sup> Steiner, *Trans. Faraday Soc.*, 1935, 31, 962.

If the above suggestion concerning the state of the surface is correct, then on raising the temperature  $p_s$  should no longer remain independent of the diameter of the bomb.

The effects noted in (3) concern the radiation emitted. Bawn and Garner<sup>3</sup> found that the amount of radiation emitted above the step depended on the nature of the surface of the vessel, although this had little effect on  $p_s$ . The radiation is emitted not only from the flame front, but also from the gases behind, and hence it is more likely to be affected by the nature of the surface than the reaction mechanism in the flame front. The temperature coefficient of the radiation from mechanism II. is therefore probably a surface effect. The amount of radiation emitted from flames containing little or no hydrogen (mechanism I.) is very great, amounting to nearly 25 per cent. of the total heat of reaction.<sup>14</sup> Garner and Johnson have suggested<sup>15</sup> that this high emission is due mainly to chemiluminescence of the freshly formed products, and that on the introduction of hydrogen one of its effects is to deactivate the freshly formed carbon dioxide molecules before they can emit radiation, *i.e.*, it converts their vibrational energy into kinetic energy. This suggestion is supported by the work of Eucken and Becher<sup>16</sup> on the conversion of translational energy of carbon dioxide molecules into vibrational energy. This process is slow for the pure gas, but rapid in the presence of hydrogen or water. The reverse process, vibrational to translational energy, is affected in a like manner. Therefore the increase in the radiant energy emitted by mechanism II. at elevated temperatures could be explained if the deactivation of the newly formed carbon dioxide molecules was less effective at these temperatures. This would mean either that collisions involving carbon dioxide were less effective or that the concentration of the deactivator or deactivators was lower. If hydrogen atoms were the deactivating agent, then their removal by the walls would account for the results obtained. This explanation, however, cannot be other than tentative, as the true cause of the reduction in the radiation emitted on passing from mechanisms I. to II. is still uncertain.

There seems to be no object in adding here to the already voluminous body of discussion on the actual atomic and molecular mechanisms of the carbon monoxide-oxygen explosion.

### Summary.

There has been investigated the effect on the radiation emitted on explosion of raising the initial temperature of  $a(2\text{CO} + \text{O}_2)$  mixture containing about 0.3 per cent. of hydrogen. It is shown (1) that heating the explosive mixture raises the pressure at which the "step" in the pressure-radiation curve appears, from which the step cannot be a lower ignition limit, and is almost certainly the pressure at which two reaction mechanisms for the flame are equally rapid, and for which two alternative explanations are suggested; and (2) that heating the quartz tube in which the explosion takes place by as little as 50° produces changes in the surface which make the step diffuse. These wall effects are discussed, and are ascribed to the removal of atoms by the walls.

## THE EFFECT OF TEMPERATURE ON THE ABSORPTION OF RESONANCE RADIATION BY SODIUM ATOMS.

BY JAMES L. TUCK AND ERNEST WARHURST.

*Received 27th July, 1936.*

The absorption of resonance radiation by sodium atoms has been used by Frommer and Polanyi<sup>1</sup> and by Fairbrother and Warhurst,<sup>2</sup> as a means of estimating the number of sodium atoms in a given reaction system. In these estimations it has always been assumed that the absorption for a particular radiation was a function of the sodium atom density only. The relationships between the absorption and the number of atoms for various light sources have been published previously (Frommer and Polanyi,<sup>1</sup> Fairbrother and Warhurst,<sup>2</sup> Fairbrother and Tuck.<sup>3,4</sup> These absorption curves have all been determined by measuring the absorption in a cell containing sodium in equilibrium with its vapour, both at the same temperature. Hence each point on such curves was taken at a different temperature.

As an addition to the above-mentioned work, the results of some experiments on the variation of absorption with temperature at constant atom density are given below.

### Experimental.

The experimental arrangement was exactly as for the measurements of Fairbrother and Tuck,<sup>4</sup> except for an alteration to the absorption cell. This consisted of the same cell but with the addition of a side-arm projecting from the body of the cell (see Fig. 1). The temperature of the main body of the cell could be varied while the side-arm was maintained at constant temperature.

Difficulties were encountered in early experiments owing to the long time for attainment of equilibrium between the sodium in the side-arm

Fig. 1

and the vapour in the main body. This was traced to the presence of residual gas. The difficulty of obtaining sodium free from residual gas is well known, and was overcome by evacuating and outgassing the cell very carefully, the sodium being outgassed by the technique given in the paper of Fairbrother and Tuck.<sup>3</sup> A diagram of the cell and heating arrangements is shown in Fig. 1. The main body of the cell, which had plane ends 4.65 cms. apart, was heated in an air-oven Z. The temperature of the cell was taken by two thermometers whose bulbs touched the cell wall. The side-arm was encased in copper foil covered with asbestos paper, over which was wound the heater. AB represents a narrow pyrex tube bound to the side-arm under the copper sheath. By introducing a thermocouple down this tube, the temperature distribution along the side-arm could be explored. For proper control of the sodium and to prevent the higher temperature of C from affecting that of the sodium, the heating of the side-arm was divided into three sections, EF, GH, and HF, the copper sheath underneath being similarly divided.

In an experiment, the main body of the cell C and the sections EF and GH were heated to 300° C. and KL kept cold. These conditions were

maintained for several hours, when GH was cooled; the absorption was found to be independent of the temperature of EF and the main body of the cell. This method of working avoided error due to sodium condensing in zones of intermediate temperature giving false readings of vapour pressure as well as taking a great deal of time for attainment of equilibrium. The readings of the photo-

tronic cell and photoelectric photometer when GH was cold gave the intensities of the incident and transmitted beams respectively and constituted an initial blank.<sup>4</sup>

The side-arm was then adjusted to a uniform constant temperature giving a suitable molar concentration, and the absorption measured for different temperatures of C, time being allowed between each measurement till a steady state was reached. At the end of an experiment KL was cooled and all the sodium distilled into it, as described above. A second blank was then taken which agreed with the first within experimental error.

The difference in temperature between the side-arm and the body of the cell introduces a small change in molar concentration in the main body with change of temperature due to the Knudsen effect. This change was corrected for by assuming the absorption to be proportional to the molar concentrations. This assumption is justified since at the low concentration used in these experiments the curve of absorption against atoms per cm.<sup>3</sup> in the beam is almost linear (see Fairbrother and Tuck).<sup>4</sup>

The results are shown graphically in Fig. 2. Percentage absorption is plotted against temperature of the absorbing vapour. The points marked  $\odot$  and  $\triangle$  correspond to different experiments. The point marked  $\oplus$  is taken from the results of Fairbrother and Tuck<sup>4</sup> and corresponds in our experiments to the cell and side-arm, being at the same temperature. Such a determination would have been difficult in these experiments, as no particular precautions were taken to prevent the condensation of sodium on the plane windows of the cell.

The results show that within experimental error the absorption of a constant number of moles decreases linearly with temperature between 140° C. and 320° C. It is to be understood that the above straight line may not be extrapolated to higher temperatures, since it is obvious that it must be asymptotic to the temperature axis.

The implications of this absorption change, in determinations of velocity constants and activation energies of reactions, by methods in which the number of atoms in a reaction zone ("Flame") is estimated from the absorption, are evident.

Hitherto the absorption by the sodium atoms in a flame has been measured at a flame temperature ranging from 200° to 300° and referred to an absorption curve taken at 110°-180° C. In the new method suggested by Polanyi and communicated in the paper of Fairbrother and Tuck,<sup>4</sup> future flame work involves the estimation of the number of atoms in a flame by measuring its total absorption. This necessitates using small maximum densities in the flame in order to confine the determinations to the linear part of the absorption curve. The above experiments are for densities in this region and thus provide all the data required for the correction of the linear parts of the curve to any flame temperature up to 320° C. Every point on the straight line (Fig. 2) gives the absorption of  $2.37 \times 10^{-13}$  moles/cm.<sup>2</sup> at a particular temperature, and since all absorption isotherms are assumed to be linear at this density, this absorption determines the slope of the absorption curve at the particular temperature. The total absorption of a flame at this temperature will hence give directly the number of atoms in it.

A tentative correction may be made of the reaction velocity constants obtained by the old absorption curves (Fairbrother and Warhurst).<sup>2</sup> Since absorption isotherms must all pass through the point  $I_t/I_0 = 1$  for  $N = 0$  and approach  $I_t/I_0 = 0$  for large  $N$ , a method of correcting absorption curves over a big range of absorption may be deduced by applying a cor-

TEMPERATURE : 244° C.

Substance.	Mean Vel. Const. $k$ in cm. <sup>2</sup> /mol. secs.	Activation Energy from Collision Yield.
PhCl	$2.66 \times 10^{10}$	10,200 cal.
PhBr	$6.08 \times 10^{12}$	4,550 "
PhI	$8.90 \times 10^{13}$	1,740 "

rection to  $\log I_t/I_0$ . This method assumes that  $\frac{(\log I_t/I_0)_{T_1}}{(\log I_t/I_0)_{T_2}}$  for big  $N$  is equal to the experimentally determined ratio at  $T_1$  and  $T_2$  for a small  $N$ .

Taking the reaction velocity constants published by Fairbrother and Warhurst<sup>2</sup> and correcting in the above manner, the results are obtained (see table).

The above figures include a minor correction for the effect of reaction vessel temperature on the carrier gas flow. It is to be emphasized that the absorption correction is of an approximate nature. The constants may be regarded as better approximations to the true velocity constants.

Our best thanks are due to Professor M. Polanyi for his interest in this work and to Dr. Fairbrother for much help and encouragement. We also wish to thank the Department of Scientific and Industrial Research for grants and the Imperial Chemical Industries Ltd. for grants towards the purchase of apparatus.

# CHEMICAL REACTION IN ELECTRIC DISCHARGES. PART I: THE STATISTICAL THEORY OF DISCHARGE REACTION.

BY K. G. EMELÉUS AND R. WINSTANLEY LUNT.

*Received 19th March, 1936.*

Whilst the facts of chemical reaction in electric discharges show that there is a close connection between the rate of reaction and the electrical conductivity of the gas, there is considerable difference of opinion about the nature of the relationship.<sup>1</sup> So many previously obscure aspects of the conductivity have been elucidated during the last thirteen years<sup>2</sup> that it now seems profitable to reconsider the problem of this relationship.

The aim of this paper is to show that a statistical treatment of the electron collision processes of the first kind which occur in discharges leads to expressions for the rate of electron collision, and for some other derived quantities, from which it is clear that all these quantities have properties in common with their experimentally determined analogues describing reaction in discharges. If, therefore, such collisions can be shown to constitute the rate determining step in the whole mechanism by which the reaction occurs, quantitative explanation is at once available for the kinetics of discharge reaction. A detailed discussion of individual reactions, which will be given elsewhere, shows that it is usually possible to find a mechanism satisfying these conditions, and that the most frequently occurring case is that in which the first step of the mechanism is a collision between a reactant molecule unaffected by the discharge and a neutral product of an electron collision with such a molecule.

We consider here the cold cathode glow discharge only<sup>\*</sup>; its chemistry and physics have been widely investigated, and other discharge forms are readily related to it. There are two zones only in this form of discharge in which much reaction is known to occur, the negative glow and the positive column (the abbreviations N.G. and P.C. will be used for these). The two experimentally determinable quantities of most interest in connection with the kinetics of discharge reaction are called the current and energy efficiencies; these express the rate of reaction in terms of the

<sup>\*</sup> Cases in which the current is used mainly for heating the reactants are not considered in this paper.

current carried by the discharge and of the energy supplied to maintain it. The principal characteristics of these efficiencies are as follows. In a given system of reactants the magnitude of either referred to a particular resultant may be widely different in the N.G. and the P.C. Their temperature coefficients are usually very small, and their absolute magnitudes may be considerable in systems where a purely thermal reaction is most unlikely and when the vessel containing the discharge is refrigerated to  $-180^\circ$ . Their pressure coefficients are usually very small in the N.G., but may be considerable in the P.C. Their variation with the current density is also very small. Lastly, in a given system of reactants, the products of a discharge may be very different from those of the purely thermal reaction.

### 1. The Current and Energy Efficiencies of Discharge Reactions.

Although these quantities have been used frequently in describing discharge reactions, it is convenient to restate their definitions, which are slightly different in the N.G. and P.C. because of the physical differences between these zones. For simplicity we consider the usual case of reaction in a cold cathode glow discharge maintained between parallel electrodes in a cylindrical tube of cross-section  $A$  cm.<sup>2</sup> and in which the P.C. occupies a length  $L$  cm. The relevant quantities experimentally measurable are :—

- $I'$  the total current carried by the discharge (as measured in the external circuit) in electrons sec.<sup>-1</sup>
- $V_N$  the potential difference in volts between the cathode and the N.G.
- $V_P$  the potential difference in volts across the P.C.
- $R'_{p,N}$  the rate of formation of reaction product in the N.G. in molecules sec.<sup>-1</sup> (the anode is so close to the cathode that the P.C. is suppressed).
- $R'_p$  the rate of formation of reaction product in the whole discharge in molecules sec.<sup>-1</sup> (the anode is so far removed from the cathode that a P.C. is present).

The rate of formation of product molecules in the P.C.,  $R'_{p,P}$ , is then given \* by  $R'_p - R'_{p,N}$ . In those regions where the current is carried exclusively by electrons, the current density,  $I$ , then follows as  $I = I'/A$ . In the case of a uniform P.C. the electric field,  $X$ , responsible for the transport of the current is then given by  $X = V_P/L$ , and the volume rate of reaction,  $R'_{p,P}$  molecules cm.<sup>-3</sup> sec.<sup>-1</sup>, is given by

$$R'_{p,P} = R'_p / (A.L.).$$

In the N.G. the current efficiency,  $\beta_{p,N}$ , is defined as the number of product molecules formed per unit charge (1 electron) carried by the current, or

$$\beta_{p,N} = R'_{p,N} / I';$$

the energy efficiency,  $\eta_{p,N}$ , is likewise defined per unit of energy (1 electron-volt) supplied to maintain this zone of the discharge, or

$$\eta_{p,N} = R'_{p,N} / (V_N \cdot I') = \beta_{p,N} / V_N.$$

\* This expression for  $R'_{p,P}$  assumes the absence of any specific influence of either the anode or the P.C. on reaction in the N.G.

In the uniform P.C. the current efficiency,  $\beta_{p,P}$ , is defined as the number of product molecules formed per unit volume and per unit current density (1 electron  $\text{cm.}^{-2} \text{sec.}^{-1}$ ), or \*

$$\beta_{p,P} = R_{p,P}/I = R'_{p,P}/(L.I'),$$

from which it will be seen that  $\beta_{p,P}$  is numerically equal to the number of product molecules formed per electron of current and per cm. length of the P.C.†, that is, per cm. of electron drift. The energy efficiency,  $\eta_{p,P}$ , is defined as the number of product molecules formed per electron-volt supplied to maintain this zone of the discharge, or ‡

$$\eta_{p,P} = R'_{p,P}/(V_P . I') = R_{p,P}/(X.I) = \beta_{p,P}/X.$$

## 2. Expressions for the Rate of Electron Collision.

In the plasma § of a discharge the plasma electrons have a distribution of velocities almost random in direction with a superposed drift in some definite direction which is responsible for the transport of charge, or current, measured in the external circuit. At the junction between a region of space charge and a plasma, or between plasmas of different kinds, the motion of the electrons is more nearly a directed flux with a distribution in velocity.

In the first case, the rate  $R$  at which some specified type of collision occurs per  $\text{cm.}^3$  per sec. between electrons and some specified type of reactant molecule (unchanged by the discharge) is given by §

$$R = k . n_e . \lambda . p \int Q(V) . V^{0.5} . f(V) . dV \quad . \quad . \quad . \quad (3)$$

where  $\lambda$  is the fractional concentration of the specified reactant molecules in a gas at the total pressure  $p$  mm. Hg,  $n_e$  the concentration of electrons per  $\text{cm.}^3$ ,  $Q(V)$  the probability cross-section for the specified type of collision with the specified reactant for an electron of energy  $V$  electron-volts,  $f(V)$  the electron energy distribution function, and  $k = 1.87 \cdot 10^9$  when  $Q(V)$  is measured as a multiple of the area of the first Bohr orbit in hydrogen (radius =  $0.53 \cdot 10^{-8}$  cm.). In the particular case that the current is carried through the plasma by the drift of the plasma electrons in an electric field  $X$ , the collision rate per unit current density,  $\beta$  collisions per cm. of electron drift, is given by

$$\beta = R/(n_e . W) \quad . \quad . \quad . \quad . \quad (4)$$

where  $W$   $\text{cms.}^{-1}$  is the drift speed of the electrons, and the collision rate per unit of energy supplied to the plasma,  $\eta$  collisions per electron-volt, is given by

$$\eta = R/(n_e . W . X) \quad . \quad . \quad . \quad . \quad (5)$$

In order to obtain the corresponding expressions for a reaction product resulting from the initial occurrence of such an electron collision, (3),

\* In the case of a non-uniform P.C. the average value of  $\beta_{p,P}$  is still given by  $R'_{p,P}/(L.I')$ , although  $R_{p,P}$  may be a function of position.

† This definition was originally given by Kirkby.<sup>1</sup> The quantity usually given in literature is  $R'_{p,P}/I' = L . \beta_{p,P}$ , which is inconvenient because it depends on  $L$ .

‡ In the case of a non-uniform P.C. the average value of  $\eta_{p,P}$  is still given by  $R'_{p,P}/(V_P . I')$ , although  $R_{p,P}$  and  $X$  may be functions of position.

§ Tonks and Langmuir, *Physic. Rev.*, 1929, **34**, 877.

¶ Fowler, *Statistical Mechanics*, Cambridge, 1928, § 17.

(4), and (5), must be multiplied by a factor  $\phi$  which denotes the number of such product molecules formed per initial electron collision. The factors controlling  $\phi$  are similar to those controlling the quantum yield in reactions initiated by the absorption of light<sup>5</sup>, together with special factors arising only in discharges; an example of the latter occurs when the products of electron collision, or reaction, formed in one zone have to pass through another zone before being isolated. It will be shown in § 4 that, when  $\phi$  is constant,  $\phi \cdot \beta$  and  $\phi \cdot \eta$  may have many properties in common with the experimentally determinable quantities,  $\beta_{p,p}$  and  $\eta_{p,p}$ .

In the second general case, at the junction between a region of space charge and a plasma, the rate,  $G$ , at which some specified type of collision occurs between an electron of a flux entering a plasma and some specified type of reactant molecule (unchanged by the discharge) is given in collisions per sec., by

$$G = I_e \int P(V) \cdot f(V) \cdot dV \quad . \quad . \quad . \quad (6)$$

where  $I_e$  is the current in electrons sec.<sup>-1</sup> carried by the flux into the plasma,  $P(V)$  the total number of collisions of the specified kind effected by an electron of energy  $V$  electron-volts before its energy falls too low for it to be able to produce the change in question in the given system of reactants, and  $f(V)$  is now the electron energy distribution function for the flux entering the plasma. If the current across the boundary is entirely one of electrons,  $I_e = I'$ , and the collision rate per unit charge carried by the current,  $\beta_f$ , in collisions per electron, is given by

$$\beta_f = G/I' \quad . \quad . \quad . \quad . \quad (7)$$

and similarly, if  $V_N$  is the potential difference necessary to maintain the flux into the plasma, the collision rate per unit of energy supplied,  $\eta_f$ , in collisions per electron-volt, is given by

$$\eta_f = G/(V_N \cdot I') \quad . \quad . \quad . \quad . \quad (8)$$

As in the previous case, the corresponding expressions for the reaction product resulting from the initial occurrence of the specified type of electron collision may be derived by multiplying (6), (7), and (8), by a factor  $\phi$  defined as before. It will be shown in § 5 that, when  $\phi$  is constant,  $\phi \cdot \beta_f$  and  $\phi \cdot \eta_f$  have again many properties in common with the experimentally determinable quantities for the formation of the reaction product,  $\beta_{p,N}$  and  $\eta_{p,N}$ .

Concerning expressions (3) and (6), it will be noticed that they relate to electron collisions occurring in *the gas phase*, and therefore, if the reactions determining  $\phi$  are homogeneous, it follows that expressions (4), (5), (7) and (8) relate to homogeneous reactions in discharges. The effect of the temperature of the reactants is twofold. Firstly, for given absolute concentrations of reactants,  $p$  (as defined on p. 1506) will vary with the temperature; alternatively, if the actual pressure be kept constant,  $R$  will tend to diminish as the temperature is increased. On the other hand,  $G$  will not vary with temperature on account of the change in the density of the gas because this does not affect  $P(V)$ . Secondly, the temperature determines the population in the rotational and vibrational states of the reactant molecules, which, in turn, determines the effective value of  $Q(V)$  and  $P(V)$ ; but since the range of

<sup>5</sup> Bonhoeffer and Hartack, *Photochemie*, Leipzig, 1933, p. 183.

temperature concerned in many experiments is both low and small,\* the population in the higher vibrational states is in any case negligible and therefore the values of  $Q(V)$  and  $P(V)$  sensibly constant. Thus, provided the pressure and temperature coefficients of  $\phi$  are small, so are also those of the current and energy efficiencies of reaction as given by expressions (4), (5), (7) and (8).

### 3. The Chemical Differences between the Positive Column and the Negative Glow.

Since each of these zones is a plasma<sup>‡</sup>, the rate of electron collision in each may be discussed in terms of expression (3) from which it may be seen that the magnitude of  $R$  is mainly determined by the magnitude of the integral involved. But the magnitude of  $R$  in turn determines the value of  $\phi \cdot R$ ; thus, if the attribution of chemical reaction in discharges to electron collisions is correct, the differences in the chemical activity of these two zones are to be sought mainly<sup>†</sup> in terms of the corresponding differences in the value of the integral in (3).<sup>§</sup>

The magnitude of the integral in (3) is mainly determined by the amount of overlap of  $Q(V)$  and  $f(V)$  considered as functions of  $V$ . The form of  $Q(V)$  is determined by the type of transition involved.<sup>§</sup> If the transition is allowed optically,  $Q(V)$  rises from zero at the critical electron energy to a broad maximum at several times the critical energy, thereafter falling off slowly with further increase in  $V$ . If the transition is disallowed optically,  $Q(V)$  has a sharp maximum a little above the critical energy. In the N.G.,  $f(V)$  has a considerable value for  $V > \text{ca. } 20$  electron-volts as well as being large for  $V < \text{ca. } 5$  electron-volts. In the P.C.,  $f(V)$  is usually inconsiderable for  $V > \text{ca. } 10$  electron-volts. It follows that, in the P.C., reactions initiated by the products of disallowed transitions will be relatively more important compared with reactions initiated by the products of allowed transitions than they are in the N.G. The absolute amount of the former type of reaction may be greater in the N.G. than in the P.C. since  $n_e$  attains its maximum value for a given discharge in the N.G. Thus, if in a given system of two reactants, the reaction product resulting from the initial occurrence of a disallowed transition suffered by one reactant is different from that resulting from the initial occurrence of an allowed transition suffered by the other reactant,

\* The temperature usually recorded is that of the surroundings of the vessel containing the discharge; this has been varied from  $-180$  to about  $200^\circ \text{C.}^1$  The actual temperature of a gas in which a discharge is passing is difficult to determine, but in many experiments it probably did not exceed that of the surroundings by more than about  $100^\circ$ .

† It is found on evaluating the integral in (3) for typical cases that its value usually has a much greater effect in determining the magnitude of  $R$  than have any differences in  $n_e$  in the two zones; and, since in many systems it is unlikely that  $\phi$  changes much, this result is independent of small variations in this quantity.

‡ The differences in chemical activity are thus attributed to the same factors that give rise to the differences in the arc spectra in these zones.

§ Whilst there are numerous data for atomic transitions<sup>6</sup>, there are comparatively few for molecular transitions which latter are of the greater importance for discharge reaction. The cases of molecular transitions examined experimentally are found to fall into the same general classifications as do the atomic ones, and since this is to be expected on theoretical grounds<sup>7</sup> there is no reason to doubt that the similarities between atomic and molecular transitions are not general.

<sup>6</sup> Hanle and Larche, *Ergeb. d. Exakt. Wiss.*, 1931, 10.

<sup>7</sup> Massey and Mohr, *Proc. Roy. Soc., A*, 1932, 135, 258; Mott and Massey, *The Theory of Atomic Collisions*, Oxford, 1933.

the foregoing considerations predict that the first-mentioned reaction product will be the principal product in the P.C. and that the two products will be formed in the N.G., the second predominating in amount: these considerations thus afford a possible explanation of the dependence of the chemical nature of the product on the zone of the discharge used.\* Similarly, if allowed transitions alone are responsible for the formation of a single product in a given system of reactants, the greater overlap of  $Q(V)$  and  $f(V)$ , and the larger value of  $n_0$ , in the N.G. leads to the prediction that the absolute amount of reaction † will tend to be greater in this zone compared with the P.C.: this at once affords a possible explanation of the observed differences between the current and energy efficiencies in these two zones.

#### 4. Reaction in the Positive Column.

The uniform P.C. is a plasma ‡ to which the expressions (3), (4), and (5) are applicable. It is nevertheless not possible to predict from these expressions with certainty any general rules for the dependence of the quantities  $R$ ,  $\beta$ , and  $\eta$ , on  $p$  and  $X$ . Furthermore, in considering the corresponding (theoretical) quantities for reaction, it may be noticed that, even if  $\lambda$  is constant,  $\phi$  itself may be a function of  $p$ , and of the radius of the tube in which the discharge occurs, if a significant part of the reaction occurs on the walls of the tube, because these quantities will determine the rate at which the primary products of electron collision will diffuse to the walls.

Since many discharge reactions appear to be homogeneous§, we shall consider this special case and assume in addition that  $\phi$  is constant, and that  $\lambda$  is constant (this being attainable with comparative ease in

\* The simplest case known is a system of one reactant, helium. The formation of triplet  $\text{He}_2$  molecules as the main product of reaction is detectable in the P.C.: the formation of such molecules can arise only as the consequence of the initial occurrence of a disallowed transition, since the ground state of helium atoms is singlet (the triplet molecule of lowest energy is derived from the combination of a  $1^1\text{S}$  with a  $2^3\text{S}$  atom). In the N.G. the formation of both singlet and triplet molecules in comparable amounts is detectable: the formation of singlet molecules arises as the consequence of the initial occurrence of an allowed transition (the lowest stable singlet molecule is derived from the combination of a  $1^1\text{S}$  with a  $2^1\text{S}$  atom, the latter being formed mainly by emission of radiation from  $3^1\text{P}$  atoms).<sup>6</sup>

† Emeléus, Cowan and Brown, *Nature*, 1931, 127, 593; Cowan, *Thesis*, Belfast, 1931; Keyston, *Phil. Mag.*, 1933, 15, 1162; Emeléus and Duffendack, *Physic. Rev.*, 1933, 44, 322.

‡ In discussing the absolute amount of reaction, it is necessary to bear in mind (*cf.* the definitions in § 1) the importance of making due allowance for the length of the P.C. which may be extended indefinitely by separating the electrodes and correspondingly increasing the potential between them.

§ In an actual discharge tube the P.C., itself a plasma, is separated from the walls by a thin sheath of space charge<sup>7</sup>: the thickness of this annulus of space charge is negligible compared with the diameter of the P.C., which fills the remainder of the tube, for the range of pressures and tube diameters which are generally used for examining reaction in glow discharges. The expressions (3), (4), and (5), relate strictly speaking, to the isotropic region forming the main bulk of the P.C., but at its boundary by the sheath and by the Faraday dark space at its "head" the conditions may be different: however, since the volume occupied by the boundary regions is (usually) inconsiderable compared with the isotropic region, it is a good approximation to consider the whole volume enclosed by the discharge tube (over the length of the P.C.) as an isotropic region of plasma.

§ There is very little evidence for the existence of heterogeneous discharge reactions.

experiment). From (3), (4), and (5) it follows that the current and energy efficiencies for the formation of a single reaction product resulting from a single electron collision process may be expressed by

$$\phi \cdot \beta \cdot p^{-1} = k \cdot \lambda \cdot W^{-1} \cdot I(V) \quad (4.1)$$

$$\text{and} \quad \phi \cdot \eta = k \cdot \lambda \cdot (W \cdot X p^{-1})^{-1} \cdot I(V) \quad (5.1)$$

where  $I(V)$  is the integral in (3). In the particular case that  $f(V)$  does not change with  $X$  and  $p$ ,  $I(V)$  may be replaced by another function,  $I_1(\bar{V})$ , where  $\bar{V}$  is the average electron energy, because  $f(V)$  may then be replaced by another function  $f_1(\bar{V})$ . For very low current densities  $\bar{V}$  and  $W$  are known, for a given gas, to be functions of  $Xp^{-1}$  only<sup>9</sup>; reasons for believing that this dependence extends to the higher current densities of P.C. discharges have been discussed by Townsend<sup>9</sup>, and have been elaborated recently by Lunt and Meek.<sup>10</sup> When  $V$  and  $W$  depend only on  $Xp^{-1}$  it follows that  $I_1(\bar{V})$  depends on  $Xp^{-1}$  only, and therefore, when  $\lambda$  is a constant, that  $\phi \cdot \beta p^{-1}$  and  $\phi \cdot \eta$  are functions of  $Xp^{-1}$  only; moreover when  $\phi$ ,  $\lambda$ ,  $Q(V)$ , and the form of the electron energy distribution function are known, the absolute values of  $\phi \cdot \beta p^{-1}$  and  $\phi \cdot \eta$  may be calculated from (4.1) and (5.1) as functions of  $Xp^{-1}$ . Since in a given gas  $Xp^{-1}$  depends mainly on  $p$  over a wide range of current density (for a given diameter of discharge tube), it follows that  $\phi \cdot \beta$  and  $\phi \cdot \eta$  will vary with the pressure but be independent of the current density over a wide range: expressions (4.1) and (5.1) thus provide a possible explanation of experimentally observed properties of the current and energy efficiencies in the P.C.\* The explanation becomes definite when the initial type of electron collision is identified, when it can be shown that a reaction mechanism exists in which the initial and rate determining step is the reaction between the product (or products) of the particular electron collisions and reactant molecules unchanged by the discharge, and which is consistent with the postulated constancy of  $\phi$ , and when it can be shown that the (theoretically) calculated dependence of  $\phi \cdot \beta p^{-1}$  and  $\phi \cdot \eta$  on  $Xp^{-1}$  is in quantitative agreement with the experimentally observed dependence of  $\beta_{p,p} \cdot p^{-1}$  and  $\eta_{p,p}$  on  $Xp^{-1}$ . It will be seen that even by the introduction of simplifying conditions no general conclusion can be reached concerning the identification of the type of electron collision the product of which initiates reaction: it is necessary to examine the theoretical and experimental data in detail in any given system of reactants before a conclusion can be reached.

In a striated P.C. the conditions are more complex.<sup>3</sup> At the head of a striation, where a directed electron flux rapidly degenerates into an almost random motion, either expression (3) or (6) may be used as in the N.G.† The head of the P.C. in this respect is similar to the head of a striation.

<sup>10</sup> Lunt and Meek, *Ionisation, Excitation, and Chemical Reaction in Uniform Electric Fields*, Part II. (*Proc. Roy. Soc.*), in the press.

\* It is noteworthy that the first observation of the dependence of the experimentally determined quantity,  $\beta_{p,p} \cdot p^{-1}$  on  $Xp^{-1}$  was made by Kirkby<sup>1</sup> when examining the formation of water from electrolytic gas; a further examination of his data shows that  $\eta_{p,p}$  was also dependent on  $Xp^{-1}$  only, and over a considerable range of current density.

† Cf. footnote \*, p. 1511.

### 5. Reaction in the Negative Glow.

Although this zone is also a plasma <sup>2</sup> it is not practicable to discuss the theoretical quantities derived for reaction in terms of the expressions (4) and (5) because in this zone the current is carried mainly by the diffusion of electrons and not by the drift due to a field; it is, therefore, convenient to discuss this zone in relation to expressions (6), (7), and (8).<sup>\*</sup> Since the field in this zone is negligibly small, there is little motion of ions or electrons across the cathode dark space—N.G. boundary except that associated with the flux of electrons from the cathode dark space, and  $I_e$  is therefore sensibly equal to  $I'$ ; for the same reason the whole energy available in the N.G. is that brought in by the flux, this is about one-sixth of the total energy supplied externally to maintain the region of the discharge extending from the cathode to the N.G. (and Faraday dark space).<sup>11</sup> Of this fraction only that part can be used for effecting excitation processes which is left over after the ionisation processes necessary to maintain the N.G. have been allowed for; this limits the amount of reaction initiated by the products of excitation processes which can occur.

For the reasons stated in the previous section we shall again consider the simple conditions arising when  $\lambda$  and  $\phi$  are constant. If the cathode fall in potential is normal,  $V_N$ ,  $f(V)$  in (6) has then average <sup>11</sup> value  $\bar{V}_f = \text{ca. } V_N/6$ , and is zero for  $V > \text{ca. } V_N$ , independent of the pressure;  $f(V)$  can thus vary little if at all with the pressure. Provided that the composition of the gas is constant, and that the dimensions of the N.G. are large compared with the electron mean free path,  $P(V)$  is also constant independent of the pressure since it is determined only by the number of collisions which an electron makes before its energy falls below the critical for the specified process. The integral in (6) is therefore practically independent of the pressure and  $G$  is proportional to  $I'$ . It then follows from (7) and (8) that  $\phi \cdot \beta_f$  and  $\phi \cdot \eta_f$  for the formation of a single product resulting from a single electron collision process are likewise independent of the pressure and the current density: expressions (7) and (8) thus provide a possible explanation of the observed properties of the current and energy efficiencies in the N.G.† The conditions under which the explanation becomes definite are now essentially the same as those stated when discussing the analogous case of reaction in the P.C. (cf. p. 1510), except that it is now necessary to show that the values of  $\phi \cdot \beta_f$  and  $\phi \cdot \eta_f$  calculated from (7) and (8) ‡ are in quantitative agreement with the experimentally determined quantities,  $\beta_{p,N}$  and  $\eta_{p,N}$ .

When the cathode fall in potential is abnormal,  $V_N$ , the average value of  $f(V)$  will still occur <sup>11</sup> at about  $V_N/6$ , but since  $V_N' > V_N$ , and  $V_N'$  varies with  $I'$ ,  $G/I'$  will no longer be necessarily independent

\* In the N.G., even when  $\lambda$  is constant, all the quantities in expression (3) for  $R$ , except  $Q(V)$ , may be functions of position. Since the actual rate of collision must be independent of any postulated mechanism by which its algebraical expression is derived, it follows that the integral of  $R$  throughout the volume through which the N.G. extends must be equal to  $G$ , as given by expression (6).

<sup>11</sup> Guntherschulze, *Z. Physik*, 1924, **23**, 334; Linder, *Physic. Rev.*, 1931, **38**, 679; Emeleús and Kennedy, *Phil. Mag.*, 1934, **18**, 874.

† Again it is interesting to note that first observations of the experimentally determined quantities,  $\beta_{p,N}$  and  $\eta_{p,N}$  were made by Kirkby.<sup>1</sup>

‡ The numerical evaluation of the integral in (6) is at present restricted to ionisation processes because for these alone <sup>12</sup> are data available for  $P(V)$ .

<sup>12</sup> Langmuir and Jones, *Physic. Rev.*, 1928, **31**, 402.

of the cathode fall in potential although it will independent of the pressure if  $V_N$  is constant (i.e.,  $I'$  constant). It is sometimes found that  $\beta_{p,N}$  is constant although  $V_N$  is varying.\* Since  $P(V)$  increases with  $V$ , this implies that less of the current carried across the boundary between the cathode dark space and the N.G. may be carried by fast electrons, and more by positive ions, as  $V_N$  increases; for this possibility there is independent evidence.<sup>13</sup>

## 6. Reaction in Other Discharge Zones.

Little attention has been paid to reaction in the cathode glow or in the Faraday dark space, but they have interesting possibilities. Spectroscopic study<sup>14</sup> of the cathode glow has shown that it may contain neutral atoms or molecular fragments of unusual types. The possibility exists of separating and utilising these in quantities approaching those which would be obtained if each, when charged, was responsible for the whole transport of current between the cathode and the cathode dark space. The Faraday dark space often has peculiar properties because of the presence of metastable atoms<sup>2, 3, 15</sup>; it is possible that some reactions attributed to the N.G. would be more correctly described as occurring in the contiguous parts of the Faraday dark space.

## Summary.

The statistical theory of electron collision processes of the first kind has been developed with particular reference to the conditions found in the negative glow and the positive column. This leads to expressions for the current and energy efficiencies of such processes which show that these quantities have the properties frequently exhibited by the corresponding efficiencies for chemical reaction in these zones of a glow discharge. The nature of the relationship between the corresponding efficiencies is outlined.

## MAGNETIC SUSCEPTIBILITY OF BINARY ALLOYS OF THALLIUM.

By (Miss) AUDREY W. DAVID AND JAMES F. SPENCER.

(Received 29th July, 1936.)

The mass susceptibility has frequently been shown to be an excellent property for the investigation of the nature of alloys, in particular the measurement of this property will indicate the existence of intermetallic compounds, change of allotropic state and change of crystalline form of the constituents of an alloy. With the object of investigating the nature

of the binary alloys of thallium, the variation of the mass susceptibility with change of composition has been measured for complete series of alloys of this metal with cadmium and bismuth, respectively. The measurements have been made with specimens of the alloys, both freshly cast and annealed in a vacuum at a temperature somewhat below the melting-point of the alloy. The measurement of the annealed specimens was undertaken because of a criticism by Shimizu<sup>1</sup> of some measurements of Spencer and John,<sup>2</sup> in which it is claimed that the divergence in the values of the two sets of measurements is due to absorbed gases in the specimens of the latter authors.

### Materials.

The bismuth and cadmium (Kahlbaum) were the purest obtainable. Analysis of the material confirmed this. The thallium on analysis was found to contain appreciable quantities of lead and bismuth, and it was purified before use. The metal was dissolved in dilute sulphuric acid, the solution filtered and allowed to crystallise. The thallium sulphate was twice recrystallised from water. The recrystallised material in about 5 per cent. solution was made slightly acid with sulphuric acid and treated with hydrogen sulphide until there was no further precipitation of lead and bismuth sulphides. The solution was filtered and boiled to remove hydrogen sulphide, and when cold electrolysed in a large flat dish using platinum electrodes, the anode being enclosed in a small porous pot to prevent the metal becoming contaminated with thallic hydroxide, which was formed in small quantities at the anode. The metal was collected and repeatedly washed with air-free water and preserved under air-free water until required. The purified metal was shown to contain less than 1.4 parts of bismuth in 10 million parts of thallium by the cinchonine-potassium iodide reaction,<sup>3</sup> and less than 0.8 parts of lead per million by the diphenyl thiocarbazon (dithizone) reaction.<sup>4</sup> All three metals were examined for the presence of iron by the thioglycollic acid reaction<sup>5</sup> and shown to contain less than one part of iron in 10 million parts of the metal.

### Preparations and Analysis of Specimens.

The alloys were cast into sticks about 9 cms. long and 0.68 cms. diameter. The metals in approximately the required proportions were melted in a graphite crucible and stirred with a silica rod. Owing to the ease with which molten thallium oxidises in air, it was found necessary, in the case of all alloys containing more than 50 per cent. of thallium to prepare the sticks in an atmosphere of nitrogen. The molten metal was poured into carbon moulds of the required diameter. After cooling the sticks of metal could generally be pushed out of the mould, because of the contraction of the alloys on solidification, in other cases the mould had to be broken to obtain the rod of alloy. The sticks of metal were rubbed with fine sand paper until they would slide easily into the measuring tubes, and then washed successively with diluted hydrochloric acid and water to remove traces of iron which may have become attached to the surface. The sticks were dried with absorbent paper and placed in a desiccator and dried over sulphuric acid in a vacuum. The sticks were then cut to a length 7.4 cms. by removing pieces from both ends, which were used for analysis. The end portions were separately dissolved in acid, tested for iron by the thioglycollic acid reaction and the solution used for the deter-

mination of the thallium content. In no case was iron detected. The thallium was determined by adding a solution of sodium carbonate to the boiling solution of the alloy, on continued boiling the whole of the cadmium and bismuth was precipitated as basic carbonate. The solution was cooled, filtered and washed with boiling water until the filtrate gave no reaction with potassium iodide solution. In the case of the cadmium alloys a 2 per cent. solution of sodium carbonate was used for washing, since hot water alone tended to peptise the basic carbonate. The filtrate and washings were brought to about 300 c.c., raised to the boiling point, and 2 grms. of finely powdered potassium chromate added for every 100 c.c. of solution. The precipitate of thallous chromate was left to settle overnight and filtered on a sintered glass crucible, washed successively with 2 per cent. potassium chromate and 50 per cent. alcohol, dried at 120° C. and weighed. The method of analysis adopted was compared with the iodide method, when it was shown the results of the chromate method were the more reliable, and almost 0.1 per cent. higher than those from the iodide method. The two ends of a stick of alloy almost invariably had an identical thallium content. No rod was used for magnetic measurement if a variation of more than 0.1 per cent. existed between the composition of the ends. The mean composition of the end pieces was taken as the composition of the alloy under measurement.

The whole of the cadmium-thallium alloys were tough and contracted on solidification, those with a high cadmium content were bright and had a silver lustre, whilst those with a high thallium content were lead-like in appearance. Bismuth-thallium alloys with a low thallium content were brittle and had a silver lustre, whilst with a thallium content above 40 per cent. the alloys were less brittle and contracted very much on solidification, they were dull in appearance and oxidised in air more rapidly the higher the thallium content.

### Measurement of Susceptibility.

The mass susceptibility measurements were made at room temperature (21°-23° C.) by the modified Gouy method, as described by Sugden<sup>6</sup> and Trew and Watkins,<sup>7</sup> using a field strength of about 5000 gauss. Five individual measurements were made of the pull of the field on the specimen and the mean of the five values, which did not vary by more than the experimental error of the method, accepted as the pull of the field on the specimen. From this value, the mass susceptibility was calculated in the usual way. The results, which may be taken as accurate to within 1.0 per cent., are recorded in the tables below. Table I. gives the mass suscepti-

### Discussion.

The mass susceptibilities of the pure metals are in general agreement with the values obtained by previous workers. The values given by Honda<sup>8</sup> were corrected for a small iron content, whilst in the present work the specimens measured did not contain an amount of iron which would affect the value obtained, and consequently the values recorded were not rendered uncertain by the application of a rather indefinite correction. The susceptibility-composition-curve for the bismuth-thallium alloys shows definite maxima at points corresponding with alloys containing 36 and 71 per cent. of thallium respectively. These compositions are those of intermetallic compounds  $\text{Bi}_2\text{Tl}_3$  and  $\text{Bi}_3\text{Tl}_2$ , respectively. The existence of these compounds is also indicated by the work of Medenhall and Lent.<sup>9</sup> The freezing-point composition curve obtained

<sup>8</sup> Honda, *Ann. de Physik*, 1910, **32**, 1027.

<sup>9</sup> Medenhall and Lent, *Physic. Review*, 1911, **32**, 406.

by Heycock and Neville<sup>10</sup> indicates the existence of  $\text{Bi}_3\text{Tl}_3$ , and these authors isolated the compound as a soft malleable mass melting at  $211.7^\circ\text{C}$ . Freezing-point curves furnish no evidence of the existence of  $\text{Bi}_3\text{Tl}_3$ , but they indicate  $\text{Tl}_3\text{Bi}$  with a transition point at  $90^\circ\text{C}$ . On the other hand, E.M.F. measurements of cells with bismuth-thallium alloys as electrodes, made by Kremann and Löbinger,<sup>11</sup> as well as a study of the thermal expansion by Omodei and an investigation of the thermoelectric properties by van Aubel<sup>12</sup> all furnish evidence of the existence of both the tri- and penta-bismuthide of thallium. The electroconductance experiments of Geuther and Shultze<sup>13</sup> support the evidence for the existence of  $\text{Bi}_3\text{Tl}_3$ , but offer no confirmation for the existence of  $\text{BiTl}_3$ , although they suggest  $\text{BiTl}_3$ . The difference between the mass susceptibility of the annealed and unannealed specimens of the bismuth-thallium alloys is quite irregular and not very large, the greatest change being about 12 per cent., whilst in many cases it does not exceed the amount of the probable experimental error of the measurement. A peculiar feature of the results lies in the fact that alloys containing less than 40 per cent. of thallium are more diamagnetic after annealing than before, whilst alloys containing more than 40 per cent. of thallium, with one exception, are less diamagnetic after annealing. Whilst the change in the susceptibility of alloys with less than 40 per cent. of thallium could be due to the removal of adsorbed oxygen, this is unlikely owing to the ease with which thallium combines with oxygen, the change in the alloys containing a higher content of thallium must be due to some other cause which is not apparent. The susceptibility-composition curve for the thallium-cadmium alloys shows no irregularities, so that it may be taken such alloys are mixtures of the constituent metals, and they have mass susceptibilities which can be calculated from the mixture law. A search of the literature furnishes no evidence at variance with this conclusion, there being no evidence to support the existence of any intermetallic compound of these metals. It was found impossible to get values for the annealed thallium-cadmium alloys which would be exactly comparable with the values for the unannealed alloys, for cadmium volatilised appreciably during the annealing. One or two values were measured, and are included in the table. These were obtained by calculating the susceptibility after the loss of weight and the change in composition had been evaluated.

# A NOTE ON THE ABSORPTION SPECTRUM OF CHLORINE.

By C. F. GOODEVE AND B. A. STEPHENS.

Received 21st July, 1936.

The measurements by Halban and Siedentopf<sup>1</sup> of the extinction coefficient curve of chlorine show a sudden rise between 579  $m\mu$  and 614  $m\mu$ , followed by a slight diminution. A total increase of over one-hundredfold was recorded, with a maximum value of the extinction coefficient at 614  $m\mu$  of 0.049 (the concentration is expressed in mols. per litre, length in cms. and the logarithms of intensities to the base 10). It would seem from these observations that a new band system appears in the red, arising from a combination with some intermediate electronic state.

We have examined the absorption of 3355 cms. layers<sup>2</sup> of cylinder chlorine at pressures up to two atmospheres and at wavelengths between the limit of the normal band system (about 600  $m\mu$ ) and the limit of the infra-red photographic plates (about 1150  $m\mu$ ). A Hilger Constant Deviation spectrograph was used. (Dispersion (6000 Å.) = 70 Å. per mm.)

No absorption was found in this region despite the fact that extinctions as low as  $5 \times 10^{-4}$  have been measured. It would appear, therefore, that the absorption found by Halban and Siedentopf, was due to the presence of an impurity or to an experimental error.

The normal band system of chlorine ( $O^+ \leftarrow {}^1\Sigma^+_g$ ) has been investigated by a number of authors and an assignment of quantum numbers has been made by Elliott.<sup>3</sup> An analysis by Birge<sup>4</sup> led him (no data given) to the conclusion that Elliott's vibrational quantum numbers for the upper state, should be reduced by two. A complete assignment based on this analysis is given by Weizel.<sup>5</sup>

With the above large optical thickness of chlorine, it was possible to find additional

members of the series, the extinction coefficients of which are very low. The wave numbers of the observed band heads are shown in the table. These bands fit, without difficulty, into the scheme of assignment as given by Birge and Weizel, part of which is shown. It is to be noted that the quantum number of the lowest vibration level of the upper state found in absorption, is 1. The extinction coefficient at the maximum of the corresponding two bands is about  $5 \times 10^{-4}$ , while that of the next two ( $\nu' = 2$ ), is about  $10^{-3}$  (the positions of the heads of these bands were difficult to determine). These values are higher than those found by Halban and Siedentopf for this range. It may be that an increase in tube length or in pressure would bring out further members of the series, but difficulties were encountered due to the absorption by minute traces of iodine. The dispersion was not sufficiently high to detect the isotope shift and the results offer, therefore, no further evidence as to the *exact* assignment of quantum numbers to the upper state, except in so far as they eliminate the possibility of the present assignment being more than one unit too high.

## THE ABSORPTION SPECTRUM OF CHLORINE HEPTOXIDE.

By C. F. GOODEVE AND B. A. M. WINDSOR.

*Received 21st July, 1936.*

The anhydride of perchloric acid,  $\text{Cl}_2\text{O}_7$ , was first isolated by Michael and Conn<sup>1</sup> and described by them as a "colourless oil." Its absorption spectrum has now been examined and approximate extinction coefficients determined.

Liquid heptoxide was prepared and purified<sup>2</sup> and condensed in a trap attached to a 30 cm. quartz absorption cell and a modified Bodenstein quartz spiral manometer.<sup>3</sup> Light from a hydrogen discharge tube passed through the absorption cell into a Hilger small quartz-spectrograph, E. 37. Spectrum photographs were taken at different pressures (different temperatures of the trap), and blanks were taken with different times of exposure.

At the highest pressure used, 85 mm., the heptoxide vapour was found to be completely transparent as far as about 3000 Å. Below this wave-length a smooth continuous absorption band set in and increased in intensity as far as could be measured, 2000 Å. No maximum was found.

In order to determine the approximate extinction coefficients microphotometer tracings were made for each exposure and compared with the blanks. The extinction coefficients,  $\alpha$  and  $\epsilon$ , have been calculated from the equation

$$\log_{10} \frac{I_0}{I_T} = \alpha pl = \epsilon cl,$$

<sup>1</sup> A. Michael and W. T. Conn, *Amer. Chem. J.*, 1900, **23**, 444.

<sup>2</sup> C. F. Goodeve and J. Powney, *J. Chem. Soc.*, 1932, 2078.

<sup>3</sup> Janet W. Goodeve, *Trans. Faraday Soc.*, 1934, **30**, 501.

where the pressure  $p$  is in mm. Hg., the length  $l$  in cm., and the concentration  $c$  in gram molecules per litre. The tracings gave overlapping sections of the extinction coefficient curve and have been fitted together into the curve shown in the Figure (the logarithms of the coefficients are plotted). In the central part of the curve the absolute values of  $\log \alpha$  may be in error by as much as  $\pm 0.1$  owing to variation in the blanks, but the relative values are probably more accurate than this. In the regions of high and of low density of the photographic plate the limits of error are however higher. The curve for these regions is indicated in the Figure by a broken line.

The absorption spectrum of  
chlorine heptoxide.

There is an interesting parallelism between the absorption spectra of the oxides of chlorine and of nitrogen. The monoxides of both show regions of continuous absorption.<sup>4,5</sup> Both the dioxides have a complex band system in the visible and near ultra-violet. The oxide of nitrogen corresponding to  $\text{Cl}_2\text{O}_7$  is  $\text{N}_2\text{O}_5$ . The absorption of the latter is continuous,<sup>6</sup> commencing also at about 3000 Å. and extending into the far ultra-violet.

## REVIEWS OF BOOKS.

**Solubility of Non-Electrolytes.** By JOEL H. HILDEBRAND. American Chemical Society Monograph. New York: Reinhold Publishing Co.; London: Chapman and Hall, Ltd., 1936. Pp. 199 (including title page and general preliminaries). Price 22s. 6d. net.

The second edition of this book has been largely rewritten in view of the accumulation of experimental data and of theories of dipole moments, intermolecular forces and non-ideal solutions since the first edition. The study is introduced by a general discussion of deviations from the laws of ideal solutions as based on Raoult's law and the Gibbs-Duhem equation, particular attention being paid to the effects of molecular volumes. A brief discussion of polarity includes Langmuir's theory of surface energies. The forces between non-polar molecules are discussed on the basis of modern quantum theory. A number of special problems, such as solvation, association, vapour pressures, solubilities, metallic solutions and partition, are discussed, ample experimental material and good applications of modern theory being introduced. The book handles a large range of topics with marked originality and success and is likely to prove as stimulating as the first edition was in its time. The price is high.

J. R. P.

**The Structure of Metals and Alloys.** By WILLIAM HUME-ROTHERY. (Institute of Metals Monograph and Report Series No. 1. Pp. 120 + 60 Figs. 3s. 6d.)

The series of monographs which the Institute of Metals intends to publish from time to time has made a good beginning with Dr. Hume-Rothery's survey of the structure of metals and alloys, which will interest many others than metallurgists. The new conceptions concerning equilibria in solid systems have so greatly altered the way of considering alloys and their transformations that metallurgists who have not followed closely the recent developments may well feel somewhat lost. This monograph, which does not deal with experimental methods, provides a compact and attractive survey of a difficult field. It is self-contained, beginning with an account of the electronic structure of atoms, molecules, and crystals, and passing to the crystal structure of the elements, typical lattices being figured and explained. A discussion of the atomic radii of the elements follows, the uses and limitations of Goldschmidt's values being clearly indicated. The next sections show the influence of the author's own work, a very full account being given of the effects of atomic diameter and of electronic constitution on solid solubility and on the form of the liquidus and solidus curves. Although some of the relations found must still be regarded as empirical, they have undoubtedly brought some degree of order into the puzzling diversity of the equilibrium diagrams of alloy systems. This is still more conspicuous in the following section, dealing with intermediate phases. Unfortunately, only a few systems have yet

been examined with enough care to make wide generalisations possible. The ordered-disordered changes in solid solutions, on which the work of W. L. Bragg has thrown much light, are among the topics which are clearly treated. The last section discusses imperfections in crystal structure, including the various hypotheses of secondary or mosaic structures and of internal flaws, in their application to metals. Each section is provided with a bibliography, and the monograph, which is well produced, presents a wealth of information, and in addition is well fitted to provoke thought.

C. H. D.

**Physikallisch-Chemisches Praktikum.** By Dr. K. FAJANS and D. Jr. WURST (Zweite Auflage). (München, 1935.) Akademische Verlagsgesellschaft. M.B.H. Pp. xvi + 230. Price R.M. 10.80.

The original edition of this practical textbook of physical chemistry has become very popular, not only in Germany, but in other countries as well. It was made more available to English-speaking students by the translation in 1930 by B. Topley, and has since been translated into other languages. It was obviously written by men of considerable experience in teaching practical physical chemistry, and required very little alteration for this second edition. The most important alterations are the deletion of the chapter on "Viscosity," the addition of chapters on "The Determination of Partition Coefficients," on "Decomposition Potentials of Electrolytes," and on "Vapour Pressures." Not everyone will approve of the deletion and there is room for criticism in these new chapters. The inclusion of the mass law relations under the partition coefficient and the very approximate solutions of Nernst are now obsolete. This is the only reference to the mass law found in the book. There is no obvious reason for the inclusion of such subjects as "Decomposition Potentials" in a modern textbook. It would have been valuable to describe a method of determining the vapour pressures of liquids at temperatures above room temperatures rather than the simple case of ether below room temperature. One would like to have seen the apparatus used for spectrophotometry brought up to date. It is surprising to note that open mercury contacts are recommended in heater circuits for thermostats.

It is pleasant to see that the inconsistent thermodynamic nomenclature so common in German textbooks has been brought into line with modern practice in the new edition. The paragraph entitled "Difficulties and Sources of Error" at the end of each chapter is a welcome help to teachers of practical physical chemistry and an incentive to students for criticism of their experiments.

C. F. G.

**Reports on Progress in Physics.** Vol. II. The Physical Society. London 1936. Pp. iv + 371. Price, 21s.

The problem of how to keep pace with modern developments is one which besets every physicist. The Physical Society offers a solution of the problem in its annual Reports on Progress in Physics, the second volume of which, dealing with work up to the end of 1934 is now under review. The general scheme follows that of the first volume. In addition to reports

on the general parts of the subject (Heat, Light, Sound, Electrical Measurements, etc.) there are also more extensive articles on special subjects such as Geophysical Prospecting, Radio-exploration of the Upper Atmosphere, and Electron Tubes, together with a very useful paper on the Electronic Charge and accounts of recent work in Atomic Physics, Quantum Theory, X-rays and Spectroscopy.

It is manifestly impossible to discuss each section separately. The points of maximum interest will naturally depend on the predilection of the reader, but he may be assured that, wherever he reads, he will find authoritative accounts, with complete references, presented in most cases in a lucid manner. There are a few articles which can hardly be read profitably without a specialised knowledge of the subject, but they are outweighed by others which will evoke immediate interest. The general impression gained from a survey of the book is that the Physical Society has attempted to serve both the general reader and the specialist and, in the main, has succeeded in this object.

The amount of material in this volume is very considerable and for many it will serve as a textbook of modern work. The physical chemist will find much valuable information in the article on Atomic Physics and in parts of the reports on X-rays and Spectroscopy.

The printing and lay-out of the book are of the high standard always associated with the Cambridge University Press. There is a change of notation which might have been avoided in the article on Surface Tension, while the discussion on the determination of the electronic charge from X-ray measurements is repeated in the section on X-ray spectroscopy. These, however, are minor criticisms of a book which should be in the hands of all who would keep abreast of recent work.

R. H. H.

**Dynamics of Rigid Bodies.** By W. D. MACMILLAN. McGraw Hill, London, 1936. Pp. xiii and 478. Price, 36s. net.

Professor MacMillan's book is a welcome addition to the literature of dynamics. Without departing from the classical doctrine and tradition, he has shown that much work has been done, on strictly classical lines, since the days when Routh's great treatise dominated the subject. Certain mathematical methods, which are even now not so widely known as they might be, are necessary weapons of attack, and the author has provided admirably clear expositions of the relevant parts of vector algebra and of matrix theory.

The book begins at the beginning, but it presupposes some knowledge of the subject in those who would make the best use of it. The chapters which deal with the fundamentals of the subject follow lines in the main well-known, though the author, like every competent and thorough teacher, has his own point of view. The chapters on the differential equations of analytical dynamics, on the canonical equations of Hamilton, and on the difficult method of periodic solutions initiated by H. Poincaré, are models of their kind. Each chapter is illustrated by a large number of examples on which the reader may try his skill, and the book may be unreservedly recommended to the advanced student.

A. F.

**The Revolution in Physics.** By E. ZIMMER. Faber & Faber Ltd., London, 1936. Pp. xiv and 240. Price, 12s. 6d. net.

There is no end to the number of works which set out to tell the inquiring layman all about the change that has come over the innocent Victorian physics beloved of our parents—a change that has converted the physicist into a sometimes unwilling, sometimes enthusiastic, and always amateurish metaphysician. The present volume must be counted among the successes. The author discusses, easily and clearly, the nature of matter and of light according to classical physics, light quanta, the structure of the hydrogen atom and of the higher atoms, quantum mechanics and matter waves, science and philosophy. Mathematics is reduced to a few algebraical symbols and the translation reads admirably well. The price is low, and the book is produced in excellent fashion.

A. F.

**The Quantum Theory of Radiation.** By W. HEITLER. The Clarendon Press, Oxford, 1936. Pp. xi and 252. Price, 17s. 6d. net.

It was the failure of classical methods in the theory of radiation which led to the introduction of the quantum of action and the peaks in the resulting astonishing development occur in 1905, 1913, and 1925, the years that mark the hypothesis of light quanta, the application of quantum theory to the atom, and the beginnings of quantum mechanics.

Professor Heitler's volume is divided into five main sections which deal with the classical theory of radiation, the quantum theory of the field *in vacuo*, the interaction of radiation with matter, radiation processes concerned with positive electrons, and the penetrating power of high-energy radiation.

The name and personality of the distinguished author are sufficient guarantees of the full and scholarly treatment of the subject. The book is by no means easy reading, and the difficulties are not all mathematical, but it is quite indispensable to the advanced student of quantum mechanics.

A. F.

**The Freedom of Man.** By A. H. COMPTON. Humphrey Milford, London. Oxford Univ. Press, 1935. Pp. xi and 153. Price, 9s.

The last few years have seen an extraordinary growth of interest in philosophical questions, and the realms of the metaphysicians have been invaded by amateurs of very varied attainments—physicists, in particular, have found that studies of "fate, free-will, fore-knowledge absolute" have very important bearings on their own subject. Perhaps it would be better to reverse the statement and to say that, in the eyes of the physicist, his own subject has important contributions to make to that branch of philosophic thought which is concerned with the problem of determinism. That is, perhaps, not quite so certain as the physicist deems it to be, but it is all to the good that he should air his views. He imparts a welcome freshness to an old topic, even though he may make, with surprise and pleasure, discoveries in the realm of philosophy that are not much younger than Thales.

In the matter of determinism, the easy way out is that of Johnson—"Sir, we know we are free, and there's an end on't." True, we *know* we are free, but is that the end on't? What does freedom mean? Does it mean that our volitions are uncaused, or undetermined? If so, there is at once an end to the logical and practical reasons for rewards and punishments which, surely, may only be given on the assumption which, pragmatically, we know to be true, that they have very considerable effect on our future actions. I am free to choose, but that freedom by no means puts out of court the question—what determines my choice?

Professor Compton has chosen some aspects of this age-old topic for his Terry lectures. The heads of his addresses are—Freedom versus Law, What Determines our Actions, Intelligence in the World of Nature, Man's Place in God's World, and Death or Life Eternal. His addresses form a thoughtful and earnest contribution to a difficult problem. They appeal to a wide public and will be read with special pleasure by his many friends on both sides of the Atlantic.

A. F.

**Advanced Laboratory Practice in Electricity and Magnetism.** By E. M. TERRY and H. B. WAHLIN. McGraw Hill, London, 1936. Pp. xiv and 318. Price, 18s. net.

This, the third edition of Terry and Wahlin, does not require much introduction to English readers. The work discusses in comprehensive fashion, laboratory methods for the measurement of current, resistance, potential, power, capacitance and inductance. It deals further with photometry and pyrometry, oscillators and amplifiers, electron tubes and fundamental radio frequency measurements.

In the present edition, some of the experiments have been revised and two new experiments, on the determination of the electronic charge and on the determination of the thermionic work function of a metal have been added.

The chapter on electron tubes has been revised "in order to give the student some familiarity with the recent electron theory of metals, in particular as it applies to thermionic emission." In this work of revision, it would have been well if some of the later methods for the measurement of fundamental quantities had been introduced.

The book is not overloaded with detail but, although in one or two instances the descriptions incline to the sketchy side, in general they are quite adequate and the volume forms a very useful laboratory manual for advanced students in physics or in electrical engineering.

A. F.

## SOME CHARACTERISTICS OF MERCURY—RARE GAS DISCHARGE TUBES.

BY H. W. MELVILLE.

*Received 27th April, 1936.*

In photochemistry, two ideals to be aimed at in the source of light are (a) constancy of output, (b) a sufficient degree of monochromatism. When dealing with sensitised reactions, the form of the exciting line or lines must also be known if the kinetics are to be studied in detail in order to derive the correct sequence of reactions comprising the total process. This is of particular importance in mercury sensitised reactions. If the exciting line is not narrow and unreversed, then the effect of added gases and of temperature on the shape of the absorption line of the mercury vapour in the reaction vessel may become so complicated that no real use of this method of initiating reactions can be made kinetically.

The usual type of mercury lamp having mercury-mercury, or mercury-tungsten electrodes with the cathode water cooled suffers from the disadvantages that it is unsteady, generates a considerable amount of heat, radiates lines besides the resonance lines at 2537 Å., 1860 Å. and emits, if the water cooling is not efficient, a partially reversed resonance line unless the additional complication of a magnet is employed to press the discharge against the walls of the lamp. Lamps with heated cathodes and tungsten anodes eliminate the majority of these disadvantages, although now it is necessary to control the temperature of the cathode accurately. This disadvantage is not, however, present in discharge lamps containing a mixture of rare gas and mercury vapour and running at some hundreds of volts A.C.

Commercial lamps of this type have been on the market for some time, consuming a small current—20 mA.—but no details regarding characteristics and outputs of bigger lamps working on this principle have been described so far as is known. The present paper gives details of the construction, operation and output of such a lamp capable of taking an input of 400 watts. The results also give a clue to the mechanism of the excitation of the mercury atoms in a discharge of this nature. Elsewhere its application to solving some problems in the exchange reactions of deuterium with hydrides will be described.

The shape and dimensions of the lamp are shown in Fig. 1. The end of the lamp is connected by a silica-soda glass joint to gas reservoirs, manometers and a pumping system. The electrodes are of iron sheet, as used in neon signs, one end being closed, welded to nickel wires and finally to 1 mm. tungsten wire which is sealed into the silica in the usual way by means of lead. The electrodes are water cooled in order to prevent the mercury pressure from rising too high. The lamp was excited from a 2000 v. transformer, the secondary current being controlled by a variable

resistance in the primary circuit. A few drops of liquid mercury were also present in the tube. Helium, neon and argon were used; the two latter gases were obtained from the British Oxygen Co. The neon contained a little helium and the argon was freed from the small amount of residual oxygen by passing over heated copper. The helium which contained some air was passed repeatedly through a charcoal tube cooled in liquid nitrogen. After each passage the charcoal was baked out at  $300^{\circ}$  in vacuo.

The absolute calibration of the lamp was carried out using as actinometric substances uranyl oxalate and monochloroacetic acid. The characteristics at different currents, voltages, etc., were determined by the less tedious method of measuring the mercury sensitised decomposition of ammonia since the lamp was designed expressly for use in sensitised reactions. The small amount of direct photodissociation was eliminated by interposing a 2 cm. layer of a 50 per cent. solution of acetic acid. The insulation tube for the decomposition of the ammonia was attached to a Pirani gauge and a mercury manometer. The procedure simply was to admit the ammonia to a pressure of about 100 mm., illuminate for the required time, condense out the ammonia with liquid air and measure the pressure of  $N_2$  and  $H_2$  by the Pirani gauge. This latter pressure was not

FIG. 1.

allowed to rise to more than 0.1 mm. so that the pressure of  $N_2$  and  $H_2$  produced is strictly proportional to the intensity of illumination. If the ammonia pressure is lower or if the decomposition is allowed to proceed further, the inhibitory effect of hydrogen tends to make the relationship between  $p_{N_2} + p_{H_2}$  and time depart from linearity.<sup>1</sup>

The variables to be considered are:—

Current, voltage, pressure, gas, temperature of lamp.

The effect of the temperature of the cooling water was not investigated as this remained at  $12 \pm 1^{\circ} C$ . When that part of the lamp exclusive of the electrode chambers is heated, practically no variation in output occurs up to as high a temperature as  $600^{\circ} C$ . Evidence for this statement will be given elsewhere. The three independent variables are the gas, its pressure and the current. The voltage is a function of all three, but fortunately it is not much dependent on the independent variables in the ranges used below.

Fig. 2 shows a set of experiments with argon in the lamp.

It will be seen, in the first place, that at a constant gas concentration the output increases with the current reaching a maximum and then

<sup>1</sup> Cf. Melville, *Proc. Roy. Soc., A*, 1935, 152, 327.

decreases. If, however, the pressure be maintained constant, the output becomes independent of current above 0.100 amp. It will also be observed that the output at constant current similarly increases with pressure and then decreases, as is seen from the lower curve, in which the results are plotted for a fixed current of 0.275 amp. Clearly there are optimum conditions for running the lamp. Besides the disadvantage of low output at low pressures, the electrodes begin to sputter at high current densities.

Experiments were also made to determine the time required for the lamp to reach a steady state, starting from cold. In one series after

FIG. 2.—Argon. At 4.8 mm. the voltage varied from 850 to 1150; at 2.4 mm. from 850 to 1250; at 0.48 mm. from 700 to 1200; at 0.24 mm. from 550 to 1050.

10 min., 0.0925 mm. of  $N_2$  and  $H_2$  had been produced; within 30 min. the rate of production had risen to 0.15 mm./10 min. and remained stationary thereafter. Check experiments have been made at intervals during three months' use and no important variation in output ( $\pm 25$  per cent.) was observed.

In a similar way the characteristics of the lamp were determined for neon. With this gas the lamp ran much cooler, more steadily, and over a wider range of pressure.

Again optimum conditions make their appearance, which are shown in Figs. 3a and 3b, where the output is plotted against current for different

FIG. 3a.—Neon; effect of current. At 60 mm. the voltage across the lamp was 1000; at 30 mm. 700 to 850; at 20 mm. 500 to 550; at 10 mm. 400 to 470; at 5 mm. 400 to 570; at 2 mm. 430 to 580; at 1 mm. 440 to 530; at 0.5 mm. 500 to 680.

FIG. 3b.—Neon; effect of pressure.

operating pressures. When the output is plotted as function of the pressure at a constant current, Fig. 3b shows that a maximum occurs at about 6 mm. and is independent of the current. It is also apparent that no advantage

could be gained by increasing the current beyond 0.2 amp. A few results for helium are plotted in Fig. 4; the optimum pressure being 5 mm.

Hydrogen was also employed, but yielded a very small output. On pumping out the hydrogen and re-admitting neon the output was only 0.1 of that previously obtained and gradually decreased with time. Pumping out and re-filling with neon improved the output. Apparently the hydrogen must have become adsorbed on the electrodes or on the sputtered iron and was only given up slowly on running the lamp. Helium proved to be more effective than neon in ridding the lamp of traces of hydrogen. Traces of hydrogen must, therefore, be rigorously excluded from the inert gas if a high output from the lamp is to be obtained.

FIG. 4.—Helium.

The fraction of the total radiation of wavelengths less than 2300 was  $\lambda$  measured by observing the rate of the direct photo-chemical dissociation. The mercury vapour was frozen out of the ammonia by a trap cooled to  $-70^{\circ}\text{C}$ . To get rid of the mercury vapour effectively the ammonia had to be passed through the trap very slowly, the total length being 20 cm., e.g., 15 c.c. at N.T.P. were passed through in 30 min. If the ammonia were passed through in a few seconds the partial pressure of the mercury was not reduced much below 0.0001 mm. For these experiments the acetic acid filter was removed. The rate of the direct decomposition was less than 10 per cent. of that of the sensitised.

Similar tests were made using the uranyl oxalate actinometer which is sensitive from 2000 to 4500  $\text{\AA}$ .<sup>2</sup> First a water filter was placed between lamp and reaction vessel and the rate of decomposition of oxalate measured. On substituting a 25 per cent. solution of acetic acid to cut out radiation of wavelength shorter than 2537  $\text{\AA}$ , the rate decreased to 70 per cent. of its previous value. Part of this reduction is certainly due to absorption of the 2537 line by acetic acid. On interposing a 3 cm. layer of  $\text{CCl}_4$  which cuts off 2537<sup>3</sup> the decomposition was reduced to 1 per cent. of its former value. Consequently at least 90 per cent. of the light emitted is at 2537  $\text{\AA}$ .

### Absolute Output.

The absolute output of the lamp was measured by means of the uranyl oxalate actinometer based on the data of Forbes and co-workers. For

<sup>2</sup> Forbes and Heidt, *J. Amer. Chem. Soc.*, 1934, **56**, 2362.

<sup>3</sup> Cf. Melville and Walls, *Trans. Faraday Soc.*, 1933, **29**, 1255.

example in one experiment the lamp was run under optimum conditions with neon as inert gas at 5 mm. pressure. The voltage was 370, the current 0.186 amp. and the input in watts 69. At a distance of 5.45 cm. an area  $1.25 \times 8.55 = 10.7$  cm.<sup>2</sup> received from one limb of the lamp  $3.8 \times 10^{17}$  quanta per second. Assuming even distribution of radiation from the lamp this corresponds to  $1.33 \times 10^{17}$  quanta per sec. per cm. length or  $8 \times 10^{18}$  total. This is equivalent to 8 watts and hence the luminous efficiency of the lamp works out at the relatively good figure of 11 per cent.

### Mechanism of the Discharge.

The nature of the output-pressure curves at constant current give the clue to the probable mechanism of the excitation of the mercury atoms. The form of these curves is exactly similar to that obtained

FIG. 5.

when the mean life ( $\tau$ ) of the metastable inert gas atom is plotted against pressure. From the results of Meissner,<sup>4</sup> Eckstein,<sup>5</sup> Ebbinghaus,<sup>6</sup> and Anderson,<sup>7</sup> it may be shown that metastable inert gas atoms are destroyed by diffusion to the walls of the discharge tube and by collisions in the gas phase with other inert gas atoms. The mean life may, therefore, be expressed by the equation

$$\tau^{-1} = B/p + Cp.$$

where  $B$  is proportional to the diffusion coefficient of metastable atoms through the gas and  $C$  is a constant containing factors such as the effective collision radius for the process which removes the metastable atom

<sup>4</sup> *Ann. Physik*, IV, 1927, 84, 1009.

<sup>5</sup> *Ibid.*, IV, 1928, 87, 1003.

<sup>6</sup> *Ibid.*, V, 1930, 7, 267.

<sup>7</sup> *Can. J. Res.*, 1930- , 2, 13; 1931, 4, 312.

to a higher (radiating) state. The value for  $B$  has been recalculated for a tube 2 cm. in diameter, and the data used to calculate the value of  $\tau$  are given in the Table.  $\tau$  is given in seconds if  $p$  is in mm.

The values of  $\tau$  have been computed for the pressure range employed in operating the lamp and are plotted in Fig. 5. It can be seen at once that not only do the forms of the curves in Figs. 2, 3 and 4 exhibit similar shapes but that in addition

Temp. °K.	Gas.	B.	C.
300	Ne	2000	1100
300	A	160	120
80	A	15	170
300	He	1350	107

the maxima occur at about the same pressures. It may be concluded therefore that the output of the lamp is governed primarily by the concentration of metastable atoms. This hypothesis is supported too by comparing the inhibiting effects of hydrogen in the neon discharge. Eckstein<sup>5</sup> found that 0.002 mm. hydrogen reduced  $\tau$  for neon to half its value at a neon pressure of 2.12 mm. and it has been mentioned above that small traces of hydrogen reduce the output considerably.

It is difficult to draw any definite conclusions from these experiments regarding the nature of the collisions between the metastable atom and the mercury atom. The latter atom requires only 4.88 volts for excitation, whereas the smallest amount of energy the helium atom can communicate is 19.7 volts ( $2^3S_1$ ), neon 16.5 volts ( $3P_2$ ) and argon 11.5 volts ( $3P_2$ ). In each case more than sufficient energy to ionise the mercury atom is available. The efficiency of the lamp is such, however, that the collisions between metastable inert gas atoms and mercury atoms must be very much greater than that between inert gas atoms involving the destruction of the metastable state. Since optimum conditions appear at about 5 mm. pressure, the mercury pressure being about 0.001 mm., the ratio of the collisions efficiencies would seem to be at least 5000 : 1.

### Summary.

Some characteristics of mercury—rare gas discharge tubes have been measured in order to find optimum conditions for the running of a tube capable of dealing with an input of 400 watts and emitting the resonance line at 2537 Å. For an input of 70 watts it has been found possible to obtain an output of  $10^{11}$  quanta per sec. At least 90 per cent. of the total radiation is at 2537 Å.

The optimum conditions occur at about the same values as those for the production of metastable inert gas atoms. Suggestions are made as to the mechanism of the collision processes taking place in the lamp on these bases.

The author is greatly indebted to Prof. E. K. Rideal for his constant encouragement during these experiments. He also thanks the Royal Commissioners for the Exhibition of 1851 for a Senior Studentship.

# THE MECHANISM OF THE FORMATION OF FOGS BY ULTRASONIC WAVES.

BY KARL SÖLLNER.

*Received 20th July, 1936.*

This paper deals with the mechanism of the formation of fogs, *i.e.* with the "atomisation" of non-metallic liquids by ultrasonics.

## I.

This phenomenon, first described by W. R. Wood and A. L. Loomis,<sup>1</sup> has not been investigated thoroughly, although the opposite phenomenon, the coagulation of smokes and fogs, has been studied.<sup>2</sup>

Wood and Loomis describe the formation of fogs by ultrasonics about as follows. In the case of such fairly volatile liquids as benzene, toluene, water, etc., it is best shown by dipping a beaker containing a little of one of these liquids in the oil over the vibrating quartz. The beaker fills rapidly with a white cloud—a fog of benzene. This fog is in a continuous tumultuous motion.

To produce fogs of less volatile liquids, *e.g.*, of transformer oil—as used for the oil bath—another arrangement must be used. A test-tube of about 2.5 cm. diameter is drawn out in the middle to a diameter of about 7 mm. The constriction must be rather thin-walled to allow large amplitudes of the transverse vibrations set up in the glass, otherwise the effect is weak, or unobservable. When this "collector" is dipped into the oil bath the oscillations of the glass are very vigorous at the constriction. If a little oil is now applied to the outside of the tube above the constriction, it "spreads over the surface and is thrown out in jets of spray resembling smoke and a dense cloud gathers about the tube." Close inspection shows that the oil on the collector gathers in more or less regular rings which form dots here and there, and the jets of spray are shot out from these dots.<sup>3</sup>

## II.

Having regard to the strong heat effects, usually found when irradiating with ultrasonics (and specially mentioned in the case of the collector by Wood and Loomis), one is inclined to consider the cause of the formation of fogs as a temporary evaporation followed by a rapid condensation. But this explanation can easily be discarded by using solutions containing a non-volatile compound, conveniently a dyestuff. Both in the beaker as with the collector—and in the latter case still more strikingly—the formation of coloured fogs is seen readily, hardly any residue of the non-volatile substance being left, after the whole liquid has

<sup>1</sup> W. R. Wood and A. L. Loomis, *Phil. Mag.*, 1927, 4, (7), 417.

<sup>2</sup> Cf., *e.g.*, O. Brandt and E. Hiedemann, *Trans. Faraday Soc.*, 1936, 32, 1101; *Kolloid Z.*, 1936, 75, 129; E. N. da. C. Andrade, *Trans. Faraday Soc.*, 1936, 32, 1111.

<sup>3</sup> As to photographs of this phenomenon, see the paper of Wood and Loomis, *loc. cit.*<sup>1</sup>

been dispersed into the air. Thus, temporary evaporation is excluded as the cause of formation of fogs.

Another, at first rather attractive, possibility may be seen in the fact that during strong local irradiation all liquids form mounds or fountains, which throw drops of the liquid into the air. Such a fountain is always seen in the oil bath at higher energies.<sup>3</sup> But the two phenomena, the oil fountain dispersing drops and the formation of a true fog, are quite different and independent of each other. They may be separated easily.

With substances of high viscosity (*e.g.*, paraffin-oil) a fountain, dispersing drops, is always found with medium and high energies, but the formation of a fog is only to be seen at such very high energies as endanger the quartz oscillator. With less viscous and more volatile substances (*e.g.*, ether, alcohol, benzene, etc.) contained in a beaker or test-tube fogs are easily formed at room temperature, or with less volatile and more viscous liquids at higher temperatures, using energy densities such as 20, 30, 40 mA. (according to the substance), which produce no oil fountain in these liquids; only the very small droplets form the fog. With increasing energy a point is reached, where, in addition to increased fog formation, a distinct fountain of liquid may be seen and with slightly higher energy, drops of considerable size are torn away and thrown into the air.

The drops dispersed by the oil fountain have with all substances diameters between several tenth and several millimetres,<sup>3</sup> whereas the fog droplets are so small that the fogs are stable for several seconds at least, often for several minutes. (Ultrasonics do not, then, at present provide a satisfactory method for preparing fogs, since other methods yield much smaller fog droplets, *i.e.*, much more stable fogs.)

The same applies to the collector. Here, due to the concentration of the energy, such vehement oscillations are set up in the constriction that substances like paraffin-oil may easily be dispersed, when the quartz vibrates only with normal energy.

At first sight one is inclined to the view that the fog droplets are thrown out from the jets, as described by Wood and Loomis.<sup>3</sup> But one wonders, how such small droplets can obtain sufficient energies to travel so vigorously through the air, whereas bigger drops, which occasionally (when much liquid is present on the collector) are thrown out, do not possess a high velocity and fall into the oil bath quite close to the collector. This is explained by the observation that strong air currents are set up in the neighbourhood of the vibrating collector;<sup>4</sup> these air currents are strong enough to push the flame of a micro-Bunsen-burner horizontally sideways, when brought close to the collector.

Obviously these air currents are responsible for the movement of the fog droplets and the whole appearance of the phenomenon. But they do not explain the primary formation of the fog droplets.

We must therefore discard the explanation that the fog droplets are simply thrown out from the surface of the irradiated liquid, as are the big drops from the oil fountain or the collector.

We emphasise that the collector shows no new features, as compared with the simple oil fountain, but provides a method of concentrating the energy for studying phenomena, which otherwise could not be obtained

<sup>4</sup> That an ultrasonic oscillator may produce air currents is a well-known fact, *cf.*, *e.g.*, A. Meissner, *Physik. Z.*, 1927, 28, 621; *Naturwiss.*, 1929, 17, 25.

without endangering the quartz. It produces quite generally strong mechanical actions; *e.g.*, it is very efficient in emulsifying, if drops of two immiscible liquids are put on the constriction.

### III.

An indication as to the true mechanism of the fog formation may be seen in the fact that the surface always becomes rippled as if it were being hit from above, just before fog formation sets in.

Previous experiments <sup>5, 6</sup> have shown that surfaces are always a locus of strong mechanical action—due to cavitation as defined earlier; <sup>5</sup> it therefore seems reasonable to assume that one is here also dealing with cavitation. To prove this two methods have always been employed: the mechanical effects disappear both when cavitation is rendered ineffective (due to lack of outside pressure), when experimenting in vacuo, and when a sufficiently high external gas pressure is applied (the liquid not being saturated with the gas) thus rendering the disruption of the liquid impossible.

Obviously the latter method cannot be applied in the present case, as the surface, where the fog is formed, is in contact with the gas, and saturation, in the extremely narrow zone with which we are concerned, occurs much too rapidly, to allow conclusive experiments. <sup>7</sup>

When experimenting in vacuo things seemed at first sight to be less simple than usual, but the final cause of the difficulties found, also explains a phenomenon of minor importance in the formation of emulsions, which has so far been inexplicable. (See below.)

Liquids with a low vapour pressure (*e.g.*, as tetraline, decaline, low viscosity paraffin-oil, etc.), behaved normally and yielded fogs at atmospheric pressure, but not when carefully degassed and sealed in vacuo in test-tubes, even with such strong irradiation that considerable fountains were formed in the liquids and large drops abundantly thrown out from the surface. The surface also lacked the characteristic rippled appearance, always associated with fog formation.

The more volatile substances, *e.g.*, ether, benzene, toluene, water, etc., however, somewhat unexpectedly yielded fogs in vacuo. This fog formation becomes stronger and stronger when the samples get warm after prolonged irradiation, and when heated intentionally to 40° or 50° C. before irradiation they yield very dense fogs.

The less volatile substances also showed fog formation when heated considerably prior to irradiation, or when heated by very prolonged irradiation. Correspondingly fog formation is not observed when the vacuum samples of ether, benzene, toluene, etc., are cooled down considerably prior to irradiation. The temperature where fog formation stops, depends upon the nature of the liquid (and to some extent upon the energy applied). Benzene and water, *e.g.*, do not yield fogs, when cooled to 4° and 0° C. respectively; ether must be considerably colder to prevent fog formation.

<sup>5</sup> *E.g.*, C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1935, **31**, 835.

<sup>6</sup> K. Söllner and C. Bondy, *Trans. Faraday Soc.*, 1936, **32**, 616; H. Freundlich and K. Söllner, *Trans. Faraday Soc.*, 1936, **32**, 966.

<sup>7</sup> For this reason all experiments with pressure <sup>5, 6</sup> have so far been performed with high columns of liquid or gel, thus preventing saturation at the critical spot. The meniscus, being in contact with the compressed gas, was always found to be a locus of cavitation. Just as the formation of fogs cannot be prevented by gas pressure, so emulsification cannot be prevented if just a drop of a second liquid floats on the top of another and gas pressure is applied.

Thus, we see that the difference between the more and the less volatile substances is only due to the temperature limit, below which the formation of fog in vacuo (more correctly its formation in the absence of a foreign gas), does not occur on irradiation.

The effect of lowering the temperature is not found in presence of a foreign gas, the influence of which may be seen even at such fairly low pressures as 20 or 50 mm. Hg, depending upon the substances under investigation, the temperature (so far it affects viscosity) and the energy applied.

The simplest explanation of these facts is to assume that cavitation may be rendered effective not only by a foreign gas but also by a sufficiently high vapour pressure of the irradiated liquid itself, acting in the same way as the "gas pressure" mentioned so often in previous papers. This theory of fog formation also agrees with the fact that the liquid/air interface has always been found to be the locus of the most intense cavitation effect.<sup>5, 6</sup>

The effect of the vapour pressure of the irradiated substances was demonstrated by the following experiment: a sealed test-tube containing, e.g., a few c.c., each of carefully degassed benzene and water, yields no emulsion on irradiation, even at very high energies.<sup>5</sup> But on heating the whole test-tube, e.g., to 50° or 80° C., emulsification sets in at once on irradiation (even with medium energy) and soon both layers of liquids are turbid, first the benzene and shortly afterwards also the aqueous phase.<sup>8</sup> It also becomes clear now why after very prolonged "irradiation in vacuo" a slight emulsification is often noticed.

One may therefore safely conclude that the formation of fogs is due to the same mechanism as all other disruptive and destructive effects in non-metallic systems, i.e. to "cavitation."<sup>5</sup> In these systems a gas pressure is always necessary to render cavitation effective; usually it is due to the presence of a foreign gas but it may also be due to the vapour pressure of the liquids themselves, provided it is not too low. Though cavitation is less vigorous it is still sufficient to produce effects. The close parallelism between emulsification and fog formation is obvious.<sup>9</sup>

<sup>5</sup> Emulsification—preferably in the aqueous phase—at increased temperature "in vacuo" is not nearly so strong as at room temperature under atmospheric (equilibrium) pressure. But emulsification under equilibrium pressure at increased temperature is also less strong than at room temperature. This may be due in part to the lower viscosity, and also to the reduced vigour of the collapse of the cavities. Emulsification "in vacuo" is increased if the whole test-tube containing the liquids is heated so that the pressure over the liquid is not reduced by condensation on the glass.

<sup>9</sup> Vehement ultrasonic vibrations may also produce fogs of liquid metals. When a drop of mercury or molten Wood's metal is allowed to run down inside a collector tube, as described before, a cloud of dispersed metal is formed inside the collector at high energies. The mechanism of this dispersion process seems to be quite different from that holding for non-metallic substances, in analogy with the difference of the two mechanisms of the formation of emulsions in water/oil and water/metal systems respectively. (Cf. C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1931, 31, 843.) The formation of metal fogs is not due to cavitation, as it occurs also *in vacuo*. Probably the liquid metal is thrown from one side to the other of the constriction, the continuous impacts breaking down the drops, the finest ones being finally driven away by the air currents thus forming a visible cloud.

#### IV.

The insight into the mechanism of fog formation by ultrasonics may be of some importance, when trying to develop this method (using liquid energy transmitters) on a technical scale or for calling forth still bigger effects.

We can now link up the breaking of quartz oscillators as it happened twice to the author at the beginning of his investigation in a reasonable manner with the formation of a strong fog in the oil bath. The latter appears when cavitation is strong in the oil bath. But when this happens the limiting value of the energy transmission is reached,<sup>10</sup> the excess energy can no longer be transmitted, the quartz oscillators vibrating more and more vigorously; finally it breaks. Quartz oscillators vibrating in air (where the energy transmission is very poor) must not be excited with more than a few watts, otherwise they crack, but in an oil bath they stand the application of several hundred watts for practically unlimited time.

Hence, to keep the quartz intact energy densities close to those where fog is formed in the oil bath are to be avoided; and a substance with a low vapour pressure at room temperature, such as paraffin-oil, is suitable as oil bath, in agreement with our experience; it ought not, however, to have too high a viscosity, as the damping of the vibrations increases with higher viscosities.

From a purely theoretical point of view it would therefore be advisable to use as oil bath a carefully degassed, not too viscous liquid with a high boiling-point under a considerably hydrostatic pressure contained in a vessel closed all round—a device not easily realised. Furthermore the ideal liquid ought to have a high specific gravity and a great sound velocity, to increase the energy transmission from one phase to the other as much as possible.<sup>11</sup>

My heartiest thanks are due to Professor H. Freundlich for his continuous interest in this work and his helpful criticism. I am also greatly indebted to Professor F. G. Donnan, F.R.S., for his generous hospitality.

#### Summary.

1. The formation of fogs of non-metallic liquids by ultrasonic waves is due to the same mechanism as all the other disruptive and destructive effects of ultrasonics, namely to cavitation, or more correctly to the vehement collapse of cavities.

2. This collapse may be brought about by an external gas pressure or in the absence of a foreign gas by the vapour pressure of the irradiated liquid itself, provided that this vapour pressure is not too small; for this reason fog formation stops at low temperatures in absence of a foreign gas.

3. The fact that the vapour pressure of irradiated liquids—in absence of a foreign gas—can effect the collapse of cavities explains also the fact that at higher temperatures the process of emulsification proceeds also “in vacuo,” i.e., in absence of a foreign gas.

4. The importance of fog formation in the oil bath for the technique of ultrasonics and for its further development is shortly discussed.

# EXPERIMENTS TO DEMONSTRATE CAVITATION CAUSED BY ULTRASONIC WAVES.

BY KARL SÖLLNER.

*Received 26th July, 1936.*

In some previous papers it has been shown that all the disruptive and destructive phenomena caused by strong ultrasonic waves in non-metallic systems must be attributed to "cavitation."<sup>1</sup>

If a liquid is by some means stretched unduly it disrupts, cavities are formed, and when now an external force, e.g., hydrostatic pressure acts upon these cavities, they collapse vehemently—according to Lord Rayleigh the total volume energy of the cavities is thus concentrated in a very small spot. This whole process, the formation and the vehement collapse of cavities, was called "cavitation."<sup>2</sup>

That cavitation occurs when irradiating a liquid system with ultrasonics of high energy was deduced from theoretical reasons and from many cases of (experimental) analogy.

Cavitation was actually observed some sixty years ago by Kundt and Lehmann,<sup>3</sup> when experimenting with sound waves, as ensues from their statement: "While the whole system was vibrating vigorously we several times noticed that the water close to the end of the vibrating rod turned turbid. Since it was entirely free from air, these small bubbles causing the turbidity could only be due to the disruption of the water (*Zerreißen in kleine Partien*) under the influence of these intense vibrations." Cavitation in a streaming liquid also was demonstrated by Osborne Reynolds.<sup>4</sup>

So far, however, cavitation has not been actually seen with ultrasonics, because we were mainly interested in two-phase systems (e.g., when studying emulsification) when experimenting with ultrasonics of high energy. The phenomenon was soon observed visually when investigating the formation of fogs,<sup>5</sup> where only a single phase is irradiated and no opacity hinders the observation as is the case when emulsions are formed.

The experiments must be carried out with degassed liquids to avoid the formation of gas bubbles when irradiating. To ensure this the liquids, contained in big test-tubes, are kept in the vacuum of a filter pump and the tube knocked with a piece of wood for a considerable time until, when the gas is driven out sufficiently, the glass tube starts vibrating and emits a musical tone. (The knocking has qualitatively the same effect, as the

<sup>1</sup> C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1936, **31**, 835; H. Freundlich and K. Söllner, *ibid.*, 1936, **32**, 966; K. Söllner, see preceding paper.

<sup>2</sup> "Cavitation" must not be confounded with the degassing action of sound waves, which is sometimes called cavitation in the literature.

<sup>3</sup> A. Kundt and O. Lehmann, *Ann. Physik* (Pogg.), 1874, **153**, 1.

<sup>4</sup> See historical introduction, C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1936, **31**, at page 836.

<sup>5</sup> See preceding paper.

sound waves—the liquid is stretched; for the same reason, superheated liquids start boiling on tapping.)

The phenomenon described below is best seen with liquids of not too high a boiling-point, *e.g.*, benzene and toluene or, preferably, water at a slightly higher temperature; nitrobenzene, *e.g.*, has to be heated (40–50° C.) to give well-visible results.

Not too short columns, 10–40 cm. high, of liquid are filled into U-tubes of moderate diameter or into long test-tubes. Before beginning the experiment it is advisable to irradiate for several minutes with high energy (100–130 mA.) to drive out the residue of gas invariably present.

When the liquid in these tubes is observed now (in transmitted light) whilst the energy applied is gradually increased, first a formation of fog is seen at the surface; with somewhat higher energy (best to be seen in narrow tubes) a few bubbles are formed at more or less regular half-wave distance from the surface, and the hissing noise, always to be heard when cavities collapse, increases. On stopping the irradiation suddenly the few bubbles rise to the surface. This hissing noise is a very helpful practical indicator as to the efficiency of irradiation. Although its loudness differs for different systems at the same intensity of irradiation since the readiness to cavitate differs with different systems—it is characteristic for each system. (So when trying to get reproducible results in a serial investigation, the test-tubes containing the different specimens are always dipped into the oil fountain in such a position that the same (maximum) noise is heard.)

With still higher energy the noise increases still more and slightly opaque and glittering zones are formed. In the narrow tubes they often have the form of a narrow funnel, which seems to be fixed to the glass wall. Obviously cavitation starts here at a spot on the wall where the disruption occurs more easily, due to some impurity, the adhesion being smaller than the cohesion of the liquid.

In these opaque zones a strong upward movement is to be seen. In the wider tubes the slightly glittering zones of opacity often move vigorously upwards and vanish suddenly. Hardly any, very small gas bubbles and in the best experiments none at all seen emerging from these zones of opacity. As soon as cavitation starts vigorous movement sets up in the interior of the liquid, as well as vigorous movement of any suspended impurities. So when experimenting with a diluted suspension in a narrow tube the zones of accumulation always formed in the middle of the tube are destroyed at once.

The whole phenomenon—although the opacity is considerably smaller—has the same appearance as the phenomenon of Osborne Reynolds mentioned above; one has the impression that the water is disrupted internally. One is obviously here dealing with the same phenomenon as described by Kundt and Lehmann<sup>6</sup> for lower sound frequencies, *i.e.*, one is observing true cavitation as defined above.

As usual<sup>6</sup> cavitation is rendered impossible, when a sufficiently high gas pressure is applied (the liquid being degassed), the zones of opacity are not formed any longer. In vacuo also the phenomenon ceases, bubbling and boiling of the liquid setting in.

### Summary.

Cavitation by ultrasonic waves may be made directly visible, if long columns of degassed liquids are irradiated with high energy. Slightly glittering zones of slight opacity, which disappear without producing gas bubbles, are formed in the liquid when it disrupts, due to the stretching by the ultrasonic waves.

## THE DIFFRACTION OF ELECTRONS BY MOLYBDENITE.

BY G. I. FINCH AND H. WILMAN.

*Received 23rd July, 1936.*

### 1. Introduction.

Impurities in one form or another are now well recognised as a source of "extra" rings in electron diffraction patterns.<sup>1, 2, 3, 4, 5, 6</sup> We have, however, recently obtained "extra" diffractions from graphite under conditions which were shown to exclude impurities as a possible origin, and have found further that such "extra" diffractions were in some way connected with the extreme thinness of the graphite flakes examined.<sup>7, 8</sup> It was concluded that these "extra" diffractions obtained from graphite were due to the fact that in thin flakes the graphite lattice, though virtually unbounded in the cleavage plane directions, is limited in the remaining dimension by the thinness of the crystal, thus giving rise to diffractions of fractional  $l$  index, and also to diffractions of integral  $l$  values, but otherwise forbidden by considerations of structure factor as applying to the unlimited lattice. The close agreement obtained between the observed and calculated spacings corresponding to the "extra" diffractions of graphite supports this view.

In a previous communication<sup>2</sup> we described the effect of rotation of a thin mica crystal about an axis perpendicular to the beam. It was then observed that the normal hexagon pattern appeared to elongate continuously with rotation of the specimen. The phenomenon was not recorded photographically, however, which was unfortunate, because the mica crystal was very thin, yet appeared to be exceptionally free from distortion and had, furthermore, been so successfully mounted in the axis of the specimen carrier stem that the crystal remained in the beam during rotation through a relatively large angle. Darbyshire and Cooper,<sup>9</sup> using bent mica crystals, sought for but failed to observe the phenomenon, which should give rise to streaks in the pattern. This

might, however, have been due to the considerable thickness of their specimen; thus Darbyshire and Cooper's mica pattern shows strong Laue zone spot intensification, and their mica crystal must therefore have been much thicker than ours. However this may be, we have since then recorded <sup>8</sup> streaks passing through diffraction spots in certain transmission patterns from graphite crystals which were so thin as to be practically transparent and colourless.

These new phenomena of "extra" diffractions and streaks obtained with very thin crystals are of such fundamental importance in their bearing upon the mechanism of electron diffraction and the interpretation of the pattern that we have turned our attention to the diffraction of electrons by other layer lattices with the object of submitting our previously advanced views <sup>8</sup> to further experimental test. In what follows an account is given of the diffraction of electrons by thin flakes of molybdenite, a mineral of relatively simple lattice structure. Patterns from mica were also obtained; though unsuitable for quantitative discussion, owing to the complexity of the structure, they served to illustrate more generally the effect of flake thickness upon the pattern.

## 2. Experimental.

Camera No. 2 (Cambridge) was used. The effective camera length and beam accelerating potential were about 50 or 28 cms. and 50 KV. respec-

FIG. 2.

FIG. 1.—Anode  
Diaphragm.

tively. A new type of anode diaphragm was employed in order to obtain the high degree of resolution aimed at as necessary for significant measurement of the diffraction patterns. A 32 S.W.G. nickel or platinum disc was perforated by driving the point of a fine needle, embedded in a cork as guide, through the disc resting on a thick sheet of aluminium. The disc was then firmly clamped in the brass diaphragm holder, Fig. 1.

Two excellent specimens of gangue-free molybdenite were selected for us by Dr. Jones from the Royal School of Mines collection. Single crystals, suitable for transmission, were prepared in the manner previously described <sup>8</sup>; they were so thin as to be translucent and varied, according to thickness, between almost colourless and dark reddish-brown.

### 3. The Structure of Molybdenite.

Molybdenite has a hexagonal layer structure.<sup>10, 11, 12</sup> The co-ordinates of the molybdenum and sulphur atoms in molybdenite are  $(1/3, 2/3, 1/4)$ ;  $(2/3, 1/3, 3/4)$ ; and  $(1/3, 2/3, u)$ ;  $(2/3, 1/3, u + 1/2)$ ;  $(2/3, 1/3, -u)$ ;  $(1/3, 2/3, 1/2 - u)$  respectively, where  $u = 0.62$ . Hence the structure may be regarded as built up of layers, each consisting of a plane hexagonal network of molybdenum atoms sandwiched in between two similar networks of sulphur atoms. The projections of the molybdenum atoms pass through the centres of interstices in the sulphur sheets, the atoms of which are directly superimposed. Successive layers are so ordered that the sulphur atoms of one layer lie on projections passing through the centres of the interstices of the sulphur sheets in the neighbouring layers. Wyckoff<sup>12</sup> gives the dimensions of the unit cell as  $a = 3.15$  Å and  $c = 12.30$  Å.

Yamaguti<sup>14</sup> and Aminoff and Broomé<sup>15</sup> have obtained electron diffraction patterns of the cross-grating type from molybdenite but observed only normal spectra.

### 4. The Results from Molybdenite.

Molybdenite crystals of in all eight different orders of thickness were examined. The corresponding colours in transmitted white light and the types of diffraction pattern yielded are given in Table I.

TABLE I.—PROPERTIES OF MOLYBDENITE TRANSMISSION CRYSTALS.

Colour.	Approximate Radius of Zero Order Zone ( $L=28$ cms. and $V=50$ KV.) in cm.	Other Features.	Estimated Order of Thickness in Å.
Almost colourless.	Indefinite, as zero and first order zones coalesced.	Brilliant cross-grating patterns, exceptionally free from background.	$\leq 40$
Very pale yellow.			$< 40$
Pale yellow.			$< 40$
Light olive-green.	1.5	First order Laue zone very faintly defined.	$\approx 40$
Olive-green.	1.0	Faint first order Laue zone. Traces of Kikuchi lines.	$\approx 100$
Dark olive-green (brownish).	0.7	Narrow first order Laue zone; a few faint Kikuchi lines.	$> 100$
Light brown.	---	Background becoming prominent; clear Kikuchi lines.	$\approx 100$
Brown.	---		
Red.	---	Strong background.	Probably $> 1000$

The thickness of the flakes of light olive-green colour was estimated from the extent of the Laue zones of bright spots in the diffraction pattern

as being of the order of three unit cells,<sup>16</sup> though in view of the double scattering which almost certainly occurs<sup>16</sup> this is probably somewhat of an underestimate. The pale yellow, very pale yellow and almost colourless flakes were evidently successively still thinner, as was shown also by the progressive increase in extent and brilliancy of the corresponding cross-grating patterns and the extreme fragility of such specimens.

(a) **Multi-spot Patterns from Thin Crystals.**—Thin, pale yellow crystals adhering by only one edge to the thicker material gave patterns, when stationary, of the type shown in Fig. 3. Even under a low magnification, it was evident in the microscope that such crystals were much crinkled and torn and, indeed, distorted to such an extent that practically all normal diffractions might be expected to occur, no matter how the crystals were set up in the beam. The analyses of Fig. 3 and of two other patterns of similar type obtained from different specimens are summarised in Table II.

and many more diffractions extending down to  $d = 0.8$  Å.

On partial rotation these distorted crystals yielded patterns of arcs, spots, streaks and faint-banded areas which were similar in type to those previously obtained from graphite.<sup>17</sup>

(b) **Patterns from Thin Crystals of Simple Uni-axial Curvature.**—Some nearly colourless or pale yellow flakes supported on two, and sometimes on three, sides by massive material were obtained. Under the microscope, in reflected light, some of these appeared to be curved about only one axis, which was parallel to the cleavage plane. Fig. 4 was obtained from such a crystal which, judging from the elongation of the central hexagon pattern, was evidently so mounted in the camera that the axis of curvature was not normal to the beam.

<sup>17</sup> Finch and Wilman, *Proc. Roy. Soc., A*, 1936, **155**, Pl. 7, Fig. 9.

FIG. 3 Transmission through distorted  $\text{MoS}_2$  flakes.  $L = 50$  cm.  
*[See page 1542.]*

FIG. 4.—Transmission through a uniaxially curved  $\text{MoS}_2$  crystal; axis of curvature parallel to cleavage plane, but inclined to beam.  $L = 50$  cm.  
*[To face page 1544.]*

FIG. 5.—Beam nearly normal to cleavage plane of a light olive green MoS<sub>2</sub> crystal. Note faint first Laue order zone.  $L = 28$  cm.

FIG. 6.—Rotation transmission through an undistorted MoS<sub>2</sub> crystal; cleavage plane inclined at 28° to axis of rotation normal to beam.  $L = 50$  cm.

[To face page 1545.]

(c) **Diffraction by Thin Undistorted Crystals.**—The thinnest (colourless, or very pale yellow) molybdenite flakes were so sensitive to injury, even by slight air currents, that the only crystals of this thickness which could be mounted in the specimen carrier without distortion or rupture were those which after cleavage spanned a cleft in a thick opaque flake and were thus well supported on at least three sides. Fig. 2 is a sketch of one such specimen which appeared to be quite flat and thus free from distortion when viewed in reflected light under the microscope. With the beam normal to and traversing the light olive-green section it yielded the pure cross-grating pattern, Fig. 5. The corresponding pattern from the yellow and colourless sections were similar, except that being almost entirely free from background they were of remarkable brilliancy and showed no signs of spot intensification, even in the first Laue order region, and were therefore considerably thinner than the light olive-green section. Spot patterns obtained from any of the three thinnest sections with the cleavage plane of the stationary crystal inclined to the beam were similar in type to Fig. 5, except that the hexagonal pattern of spots was elongated in the direction of inclination.

(d) **Rotation Patterns from Undistorted Crystals.**—The above and other undistorted crystals were mounted as accurately as was found practicable with the cleavage plane in the axis of the specimen carrier stem, which was rotated during exposure through a range of up to about  $50^\circ$  on each side of the position where the cleavage plane was normal to the beam. Fig. 4 was obtained, as stated in § 4(b), with a stationary crystal exhibiting simple curvature; but it is also characteristic, in so far as concerns the elongated streaks, of the type of partial rotation pattern recorded with an undistorted crystal mounted with the cleavage plane in the axis of rotation. In further experiments, similar rotation patterns were obtained from these undistorted flakes, the axis of rotation being still normal to the beam and passing through the crystal which, however, had been so mounted that the cleavage plane was inclined more or less steeply to the axis of the carrier. In the case of the patterns Figs. 6 and 7, the cleavage planes were at angles of about  $28^\circ$  and  $70^\circ$  respectively to the axis of rotation.

The spacings of the diffractions visible on several of the streaks in Figs. 6 and 7 agree reasonably well with corresponding values incorporated in Table II. Not only normal but "forbidden" and "fractional order" ("extra") diffractions were also well represented but, owing to the intensity of the streaks and the elongation of the spots produced by tolerance, these relatively weak diffractions do not lend themselves to such accurate measurement as do patterns of the type reproduced in Fig. 3. The corresponding spacing determinations have accordingly not been incorporated in Table II.

(e) **The Effect of Crystal Thickness on the Patterns.**—Figs. 4, 6 and 7 have in common the remarkable feature of continuous lines joining up groups of diffractions. In all these cases the crystals were so thin that little or no signs of Laue zone spot intensification could be detected. These streaks do not appear in otherwise similar patterns from molybdenite specimens which were sufficiently thick to show clear Laue zone effects. Thus in rotation patterns from translucent olive-green crystals, continuous lines were only occasionally faintly visible and were completely absent in the case of the dark olive-green, light brown and still thicker crystals, but became increasingly well-marked on proceeding from the light olive-green to the colourless crystal sections.

## 5. The Axial Ratio of Molybdenite.

The observed values of the spacings as set forth in Table II. lead to a correspondingly accurate value of the axial ratio of molybdenite in the form of thin crystals. Taking  $d_{(110)} = 1.575 \text{ \AA.}^{18}$  and combining with  $d_{(101)}$  and  $d_{(111)}$ , where  $l$  is  $\angle$  and preferably  $> (h + k)$ , in order to take advantage

of the greater accuracy of large angle intersections, we obtain in the manner previously described <sup>8</sup> the values for  $c/a$  as set forth in Table III.

TABLE III.—THE AXIAL RATIO OF MOLYBDENITE IN THE FORM OF THIN CRYSTALS.

$$c/a = \{l^2/[a^2/d_{hkl}^2 - 4(h^2 + k^2 + hk)/3]\}^{1/2};$$

$d_{(110)}$  taken as = 1.575 Å,  
i.e.,  $a = 3.150$  Å.

$d$ in Å.	Indices.	$c/a$ .
2.271	103	3.906
2.037	104	3.891
1.827	105	3.904
1.636	106	3.894
1.477	107	3.903
1.341	108	3.910
1.224	109	3.913
1.122	1.0.10	3.908
1.526	112	3.908
1.403	114	3.918
1.249	116	3.906
1.097	118	3.887

Mean value of  $c/a = 3.904$

Hence by electron diffraction the mean value of  $c/a = 3.904$  in the thin crystal, compared with 3.905 found by X-rays for the massive substance. Since any appreciable Lennard-Jones effect is most unlikely in the cleavage plane directions,  $a$  should be independent of crystal size; we may therefore conclude that the value of  $c$  is independent of the crystal thickness, because the X-ray results were obtained with relatively thick crystals.

## 6. Diffraction by Mica.

Transmission specimens of quite exceptional area could be cleaved from high-grade "ruby" mica of Indian origin, a particularly good batch of which was recovered from a broken-down high-tension condenser. The flakes were picked up on wire frames, lightly smeared with "Seccotine" and suitably shaped to support the crystal from two opposite sides. The appearance of such films and the types of diffraction patterns yielded on trans-

mission are classified for brevity in Table IV.

Although the areas of the largest molybdenite specimens were in general much less than those of the mica films of approximately similar thickness, it will be seen on comparing Tables II. and IV. that what were in all likelihood much the thinnest flakes were obtained from molybdenite. Thus, whilst with molybdenite no great difficulty was experienced in obtaining three grades of thickness decreasing from that giving rise to faint signs of Laue zones, with mica we have only twice succeeded in cleaving and mounting an undistorted crystal exhibiting no first Laue zone effects and of an area sufficiently exceeding the beam cross-section for purposes of rotation.

The rotation patterns yielded by the two thinnest undistorted mica crystals reproduce in all essentials the phenomena observed in the case of molybdenite. Thus the thinnest mica crystal obtained in the course of these experiments gave rise to a pattern recording strongly marked streaks joining families of diffraction spots; when the thickness was such, however, that even faint signs of Laue zones were in evidence the streaks disappeared, although the spots were elongated in the directions which would have been followed by the streaks. To illustrate the results obtained with such a mica crystal and with molybdenite of similar thickness, i.e., olive green in colour, it will suffice to reproduce the pattern, Fig. 8, obtained by partial rotation of a practically undistorted mica crystal about an axis normal to the beam but inclined to the cleavage plane. It is easily seen that, in addition to a slight arcing, the origin of which is discussed in § 7, the diffractions are elongated in the direction of the curves upon which the different groups of spots lie. This is the tolerance effect which, though not then photographically recorded, had previously been described by Finch, Quarrell and Wilman.<sup>8</sup>

## 7. Discussion.

In addition to spectra which are normal in that they agree with those obtained with X-rays, many anomalous diffractions from molybdenite have been observed and are recorded in Table II.

Turning to Figs. 4, 6 and 7, in which the streaks are such prominent features of the patterns, we observe in the first place that these all pass through related series of diffractions and, indeed, that no isolated diffractions are to be found elsewhere than on the streaks and, since some of the spots on the streaks are anomalous diffractions, it follows that this fact by itself, like others previously recorded,<sup>8</sup> renders untenable any explanation of the "extra" diffractions in terms of impurities.

By postulating a slipping of cleavage planes into irregular alternations of the two possible close-packing arrangements of neighbouring layers, brought about by the operation of shearing forces during cleavage of a thin molybdenite crystal, we can conceive of a stable structure being formed which has no true unit cell. Such a structure would continue to give the normal cross-grating type of pattern at any setting, but whilst the diffracted rays from some of the superposed cross-gratings would reinforce to yield all possible diffractions of the normal unit cell of integral  $h$ ,  $k$  and  $l$  values, both normal and forbidden by structure factor,

others would give rise to anomalous diffractions in positions corresponding, for the normal unit cell, to fractional  $l$  index values. Several facts, however, appear to negative any such explanation of the origin of the anomalous diffractions. In the first place, it would seem most unlikely that such slipping could have occurred in an undistorted crystal flake securely supported on three sides, as shown in Fig. 2. Furthermore, one would reasonably expect such slipping either to change substantially the value of the axial ratio as a whole or to make it indefinite, which is contrary to what has been set forth in § 5. Finally, the facts relating to the thickness of the crystals examined lead to a further cogent argument against the supposition of slip distortion of the crystal as being responsible for the anomalous diffractions. Thus, with the light olive-green flakes, the breadth of the Laue zero order suggested a thickness of about 40 Å. though, owing to the possibility of a pronounced double scattering, this may be somewhat of an underestimate. Since, however, three lesser grades of thickness than this have been obtained, it is almost certain that the thinnest, practically transparent crystals cannot have been more than three or four layers thick. Hence, no matter what slip-distortion into close-packing (and any other arrangement would be either metastable or unstable) be postulated, it does not seem possible with so few layers to account for more than a few of the anomalous diffractions in this way.

We are thus driven to fall back upon the view previously advanced in explanation of the anomalous diffractions encountered in the case of graphite.<sup>8</sup> Such diffractions fall into two groups. Integral indices have been assigned to the one group, conveniently termed "forbidden" diffractions, in the sense that their occurrence conflicts with the structure factor considerations as normally derived from the massive crystal, *i.e.*, a space lattice extending virtually to infinity in all directions. Thus the normal structure amplitude,  $S$ , is given by

$$S = A = \overline{M}_0 [2 \cos \pi(h + k + l) \cdot \cos \pi(h/3 - k/3 + l/2)] \\ + \overline{S} [2 \cos \pi(h + k) \cdot \cos \pi(h/3 - k/3 - 2ul) \\ + 2 \cos \pi(h + k + l) \cdot \cos \pi(h/3 - k/3 + 2ul)],$$

where  $\overline{M}_0$  and  $\overline{S}$  are the scattering powers of the molybdenum and sulphur atoms respectively, because  $B$ , the term involving the sines, is clearly always zero. Hence for  $11l$  type diffractions we have

$$A = \overline{S} \cdot 2 \cos 2\pi ul [1 + \cos \pi(l + 2)].$$

Thus the  $111$ ,  $113$ ,  $115$ , etc., diffractions are forbidden and do not occur with the massive crystal. The fact that they do, however, appear in our electron diffraction patterns from very thin crystals is reasonably explained in terms of the limitation of the lattice, and hence of incompletely developed periodicities, in directions other than those of the cleavage plane resulting in relaxation of the structure factor restrictions. It is quite possible, and indeed likely, that double scattering also contributes to the intensity of the "forbidden" diffractions.<sup>9, 16, 18, 19, 20</sup>

The occurrence of the second kind of anomalous diffraction, conveniently termed "extra" or "fractional order," is also to be accounted for in terms of the same theory. In this case, however, though double

<sup>18</sup> Raether, *Z. Physik*, 1932, **78**, 527.

<sup>19</sup> Shinohara, *Physic. Rev.*, 1935, **47**, 730.

<sup>20</sup> Beeching, *Phil. Mag.*, 1935, **20**, 841.

scattering may still affect the intensities of the "extra" diffractions by tending to even out the intensity distribution, it cannot of course in any way lead to their formation.

The considerations leading to the derivation of the fractional order indices for molybdenite are again based on the theorem,

$$uh + vk + wl = 0,$$

where  $u$ ,  $v$ ,  $w$ , are not only the indices of a zone axis to which the  $(hkl)$  plane belongs, but are also possible values of the beam indices when fast electrons are being diffracted by the corresponding family of parallel net planes;  $u$ ,  $v$ ,  $w$ ,  $h$  and  $k$  can have any integral values, irrespective of whether  $l$  thereby becomes fractional or otherwise, because, owing to the thinness of the crystal, the lattice is limited in the  $l$  direction, but is of virtually unlimited extent in the  $h$  and  $k$  directions. The indices,  $h$  and  $k$ , define the intersection of  $(hkl)$  with the cleavage plane; both must be integral for  $(hkl)$  to pass through atom rows in the cleavage plane, and must be small for these to be main rows. By assigning a range of probable values to  $u$ ,  $v$ ,  $w$ ,  $h$  and  $k$ , we can identify the atom rows in a diffracting plane family which must be parallel to the beam to give rise to any particular "extra" diffraction but, owing to the fact that the lattice limitation in the  $c$  direction, *i.e.*, the flake crystal thickness, is not known accurately, it is difficult to allow even qualitatively for the influence of the structure factor of the limited lattice upon the intensity of the fractional order diffractions. Hence, and bearing in mind also the added uncertainty introduced by double scattering, we consider it prudent not to rely on the relative intensities of the "extra" diffractions, but find that the theoretical spacings calculated from the indices arrived at in the above-outlined manner agree so satisfactorily with the experimentally determined spacings of the recorded fractional order diffractions as to afford further strong support of the theory of the origin of fractional orders as first put forward in the case of graphite.

From Table II. it will be seen that a series of anomalous diffractions, all lying within the 100 diffraction, still remain unexplained. Like the other "extra" and "forbidden" diffractions, however, they cannot be ascribed to impurities because they are not sporadic, but are a characteristic feature of all patterns so far obtained from strongly distorted; extremely thin molybdenite crystals. On the other hand, we have never observed these innermost extra diffractions with undistorted crystals, even on rotation. Thus it would seem that these innermost diffractions are in some way connected with changes brought about in the diffraction conditions or in the lattice by the extreme degree of distortion represented by crinkling.

With regard to the origin of the streaks, it has been already noted that they pass through families of diffractions. Furthermore, it has also been pointed out that in rotation patterns they are prominent only when the crystals are very thin, and that with increasing thickness they become weaker. Hence we interpret these streaks as the result of a space lattice limitation in the beam direction which has proceeded nearly to the lowest possible limit, *i.e.*, one layer in thickness. A single cleavage layer of molybdenum sulphide molecules would on rotation behave essentially like a true cross-grating and give practically continuous diffraction lines. The fact, however, that diffraction spots do appear on even the most intense streaks, shows that the thinnest crystals must have been at least two layers thick.

The sharpness of the streaks, as shown for example in Figs. 4, 6 and 7, is proof of the perfection of the atomic lattice in each sheet and of the exact similarity of the hexagonal arrangement in all the sheets of the crystal, even in the thinnest flakes so far obtained.

The occurrence of the prominent two-dimensional diffraction streaks in patterns from very thin rotated undistorted, and from curved stationary single crystals which we have now recorded in Figs. 4, 6 and 7 and the extension of the spots in Fig. 8 confirm the existence of the tolerance effect previously noted by us.<sup>2</sup> Darbyshire and Cooper's<sup>3</sup> failure to repeat those observations with a curved crystal is now seen clearly to have been due to its having been too thick. The elongation of the spots and the direction in which it occurs is such as to establish the existence of a pronounced tolerance effect, even with a crystal which was actually sufficiently thick to show well-marked, though rather broad Laue zone effects, and which was therefore too thick to give rise to continuous streaks on rotation. With still thinner crystals the effect of tolerance becomes even more pronounced; the arrows point in Fig. 4 to a streak of high and uniform intensity and about 3 mms. long.

That such pronounced tolerance effects can and do arise in the case of thin crystals must have important effects on patterns from random crystal aggregates and more particularly from polycrystalline specimens exhibiting one degree of orientation. Thus, for example, rotation of the pattern, Fig. 4, about the beam would give rise to a series of circular bands with more or less well-defined limits swept out by the streaks, and to rings of an abnormal breadth. This last phenomenon introduces an additional uncertainty into the problem of the estimation of particle size from ring-broadening, though it may be pointed out that when this is due to tolerance it takes place outwards, whilst broadening due to particle size of stationary crystals must occur practically symmetrically about the normal ring position.

The dark, so-called "extinction" ring previously observed<sup>21</sup> with a polycrystalline mica specimen may well be due to the close approach of the outer head of an inner band swept out by a streak family to the inner head of a similar band but of larger diameter.

The peculiar curvature of the streaks obtained from undistorted crystals rotated about an axis inclined to the cleavage plane, can be accounted for quantitatively. The problem is to determine the loci of the intersections with the screen of rays diffracted from a rotating plane cross-grating. We will first consider the perfectly general case of the grating inclined to the axis of rotation which itself may be at any angle to the beam, as follows:—

In the reciprocal lattice construction for the directions of the diffracted beams, the pure cross-grating crystal lattice is represented by a system of continuous parallel lines passing through points of the normal reciprocal lattice of the true three-dimensional crystal which lie on rows normal to the plane of the cross-grating. The directions of the diffracted beams are then obtained in the usual way by joining the points of intersection of each of these lines with the Ewald "sphere of reflection," of reciprocal wave-length radius, to its centre at this distance, *i.e.*,  $1/\lambda$ , from the origin of the reciprocal lattice and in the direction of the beam source. In view of the short electronic wave-length and the small angles of diffraction, the section of the sphere involved may with sufficient accuracy

<sup>21</sup> Finch, Quarrell and Wilman, *Trans. Faraday Soc.*, 1935, 31, Pl. 13, Fig. 35

be regarded as plane. In the present case of molybdenite the cross-grating is a (001) plane of atoms, and a particular ( $hk$ ) line of its reciprocal lattice is represented by the line  $PL$  (Fig. 9) distant  $r$  from the origin  $O$  of the lattice;  $PL$  and  $ON$  are normal to the cross-grating plane. Suppose the electron beam direction be along  $ZO$  (Fig. 10) and the axis of rotation of the crystal be  $OY_1$ , making an angle  $(90 - \delta)$  with  $ZO$ . Take as three orthogonal co-ordinate axes the directions  $OZ$  and  $OY$  in the plane of  $OZ$  and  $OY_1$ , and  $OX$  perpendicular to  $OZ$  and  $OY$ . The Ewald sphere of reflection is then represented by the  $OXY$  plane, tangent to it at the origin  $O$ , and we require the locus of the point of intersection of the line  $PL$  with the plane  $OXY$  as  $PL$  rotates with the cross-grating about the axis  $OY_1$ .

Let the cross-grating normal  $ON$  be inclined at an angle  $\xi$  to the axis of rotation  $OY_1$ . Take another set of orthogonal axes formed by  $OX_1$  along  $OX$ ,  $OY_1$ , and  $OZ_1$  perpendicular to  $OX_1$  and  $OY_1$ , and consider

FIG. 9.

FIG. 10.

the position of the cross-grating in which  $OP$ , the perpendicular from  $O$  to the  $(hk)$  reciprocal lattice line, lies in the  $OX_1 Y_1$  plane at an angle  $\eta$  to  $OY_1$ . The values of  $\xi$ ,  $\eta$ ,  $\delta$  and  $r$  are constant for a given  $(hk)$  line and a given orientation of the rotation axis relative to the cross-grating and to the beam direction.

$P$  has co-ordinates  $(r \sin \eta, r \cos \eta, 0)$ , and the direction cosines of  $OP$  with respect to  $OX_1Y_1Z_1$  are equal to  $(\sin \eta, \cos \eta, 0)$ . The line  $PL$  passes through  $P$  and, if its direction cosines are  $(u, v, w)$ , its equation with respect to  $OX_1Y_1Z_1$  is

$$\frac{x_1 - r \sin \eta}{14} = \frac{y_1 = r \cos \eta}{11} = \frac{z_1 = d}{10} \quad . \quad . \quad (I)$$

whence  $d^2 = x_1^2 + y_1^2 + z_1^2 + r^2 - 2x_1r \sin \eta - 2y_1r \cos \eta$ .

Thus the co-ordinates  $(x_1, y_1, z_1)$  of any point  $Q$  on  $PL$  must satisfy these relations, and the distance from  $P$  along  $PL$  to  $Q$  is  $d$ . The values of

$(u, v, w)$  are given by the relations

$$\left. \begin{aligned} u \sin \eta + v \cos \eta &= 0, \\ v &= \cos \xi, \\ u^2 + v^2 + w^2 &= 1; \end{aligned} \right\} \quad . \quad . \quad . \quad (2)$$

and the first expressing the fact that  $PL$  is perpendicular to  $OP$ , and the second that  $PL$  always makes an angle  $\xi$  with  $OY_1$ . Hence

$$\left. \begin{aligned} u &= -\cos \xi \cot \eta, \\ v &= \cos \xi, \\ w &= \{1 - (\cos^2 \xi / \sin^2 \eta)\}^{\frac{1}{2}} \end{aligned} \right\} \quad . \quad . \quad . \quad (3)$$

The co-ordinates of  $Q$  are, from (1),

$$\left. \begin{aligned} x_1 &= ud + r \sin \eta, \\ y_1 &= vd + r \cos \eta, \\ z_1 &= wd. \end{aligned} \right\} \quad . \quad . \quad . \quad (4)$$

and On rotation of the cross-grating and its associated reciprocal lattice lines about  $OY_1$ , the point  $Q$  moves round a circle of centre  $T$  on  $OY_1$ , where  $QT$  is perpendicular to  $OY_1$  and of length  $r_1$ , so that

$$x_1^2 + z_1^2 = r_1^2, \quad . \quad . \quad . \quad (5)$$

where  $r_1$  is a function of  $y_1$ . The line  $PL$  always lies in the surface of a hyperboloid of revolution round  $OY_1$ , whose equation is obtained by finding the value of  $r_1$  in (5) by substitution of  $x_1$  and  $z_1$  from (4), followed by elimination of  $d$  in terms of  $y_1$  from the second equation of (4). The equation of the hyperboloid with respect to  $OX_1Y_1Z_1$  is thus

$$(x_1^2 + z_1^2) \cos^2 \xi - y_1^2 \sin^2 \xi + 2y_1 r \cos \eta - r^2 (\cos^2 \xi + \cos^2 \eta) = 0, \quad (6)$$

and the locus of the point of intersection of  $PL$  in  $OXY$  is clearly the curve of intersection of this hyperboloid with the plane  $OXY$ . This curve, like any intersection of a quartic with a plane, is a conic.

For the transformation of the axes from  $OX_1Y_1Z_1$  to  $OXYZ$  we have the relations,

$$\left. \begin{aligned} x_1 &= x, \\ y_1 &= y \cos \delta + z \sin \delta, \\ z_1 &= -y \sin \delta + z \cos \delta \end{aligned} \right\} \quad . \quad . \quad . \quad (7)$$

and The hyperboloid referred to  $OXYZ$  now has the equation

$$\begin{aligned} (x^2 + y^2 \sin^2 \delta - 2yz \sin \delta \cos \delta + z^2 \cos^2 \delta) \cdot \cos^2 \xi - (y^2 \cos^2 \delta \\ + 2yz \sin \delta \cos \delta + z^2 \sin^2 \delta) \cdot \sin^2 \xi + 2r \cos \eta (y \cos \delta + z \sin \delta) \\ - r^2 (\cos^2 \xi + \cos^2 \eta) = 0, \end{aligned}$$

and its intersection with the  $OXY$  plane,  $z = 0$ , is

$$x^2 \cos^2 \xi + y^2 (\sin^2 \delta - \sin^2 \xi) + 2yr \cos \eta \cos \delta - r^2 (\cos^2 \xi + \cos^2 \eta) = 0 \quad (8)$$

Transfer the origin to the centre  $O'$  ( $x_0, y_0$ ) of this conic; then equation (8) becomes

$$\begin{aligned} (x + x_0)^2 \cos^2 \xi + (y + y_0)^2 \cdot (\sin^2 \delta - \sin^2 \xi) \\ + 2(y + y_0) r \cos \eta \cos \delta - r^2 (\cos^2 \xi + \cos^2 \eta) = 0, \\ \text{i.e., } x^2 \cos^2 \xi + y^2 (\sin^2 \delta - \sin^2 \xi) + 2xx_0 \cos^2 \xi + 2y[y_0 (\sin^2 \delta \\ - \sin^2 \xi) + r \cos \eta \cos \delta] + x_0^2 \cos^2 \xi + y_0^2 (\sin^2 \delta - \sin^2 \xi) \\ + 2y_0 r \cos \eta \cos \delta - r^2 (\cos^2 \xi + \cos^2 \eta) = 0. \end{aligned}$$

For  $(x_0, y_0)$  to be the centre, the coefficients of  $x$  and  $y$  must vanish. Therefore,

$$x_0 = 0; \quad \text{and} \quad y_0 = -r \cos \eta \cos \delta / (\sin^2 \delta - \sin^2 \xi) \quad (9)$$

The equation referred to the centre  $O'$  as origin is thus:—

$$x^2 \cos^2 \xi + y^2 (\sin^2 \delta - \sin^2 \xi) - r^2 [\cos^2 \xi + \cos^2 \eta + \cos^2 \eta \cos^2 \delta / (\sin^2 \delta - \sin^2 \xi)] = 0,$$

$$\text{i.e.,} \quad \frac{x^2}{\frac{r^2}{\cos^2 \xi} \left( \cos^2 \xi + \cos^2 \eta + \frac{\cos^2 \eta \cos^2 \delta}{\sin^2 \delta - \sin^2 \xi} \right)} + \frac{y^2}{\frac{r^2}{\sin^2 \delta - \sin^2 \xi} \left( \cos^2 \xi + \cos^2 \eta + \frac{\cos^2 \eta \cos^2 \delta}{\sin^2 \delta - \sin^2 \xi} \right)} = 1 \quad (10)$$

This is, in general, an ellipse or a hyperbola according to whether  $(\sin^2 \delta - \sin^2 \xi)$  is positive or negative, i.e.,  $|\delta|$  is  $>$  or  $<$   $|\xi|$ , since  $0 < \xi < 90^\circ$ , and  $-90^\circ < \delta < +90^\circ$ .

In the case of our undistorted single crystal rotation experiments, the axis of rotation  $OY_1$  is normal to the beam ( $OZ$ ), so that  $\delta = 0$ ; thus, the locus of the  $hk$  intersection with the plane  $OXY$  is given by:—

$$\frac{x^2}{\frac{r^2}{\cos^2 \xi} (\cos^2 \xi + \cos^2 \eta - \cos^2 \eta / \sin^2 \xi)} - \frac{y^2}{\frac{r^2}{\sin^2 \xi} (\cos^2 \xi + \cos^2 \eta - \cos^2 \eta / \sin^2 \xi)} = 1 \quad (11)$$

If  $(\cos^2 \xi + \cos^2 \eta - \cos^2 \eta / \sin^2 \xi) = 0$ , i.e.,  $\sin^2 \xi - \cos^2 \eta = 0$ , i.e.,  $(90^\circ - \xi) = \eta$ , then this locus reduces to a pair of straight lines with the equations,  $y = \pm x \cot \xi$ . In all other cases, the locus is always a hyperbola (e.g., Fig. 11), whose centre  $O'$  lies on the axis  $OY$  at a distance  $r \cos \eta / \sin^2 \xi$  from the origin  $O$ , and whose axis is parallel to either  $OX$  or  $OY$  according to whether  $(\sin^2 \xi - \cos^2 \eta)$  is positive or negative, i.e., whether  $(90^\circ - \xi)$  is  $>$  or  $<$   $\eta$ . Since the centre of the hyperbola is on the co-ordinate axis  $OY$ , i.e., the projection of the rotation axis, the hyperbolæ for which  $(90^\circ - \xi)$  is  $<$   $\eta$  must all have  $OY$  as their common axis, and therefore form a small coaxial group which should be, and are indeed, recognisable in the diffraction patterns. The equations of the asymptotes are  $y = \pm x \cot \xi$ , referred to the centre  $O'$  as origin. If the axis of the hyperbola is parallel to  $OX$

FIG. 11.

the length,  $A$  (Fig. 11), of the semi-axis of the hyperbola is

$$\{r^2 (\cos^2 \xi + \cos^2 \eta - \cos^2 \eta / \sin^2 \xi) / \cos^2 \xi\}^{\frac{1}{2}} = r(1 - \cos^2 \eta / \sin^2 \xi)^{\frac{1}{2}};$$

or if the axis of the hyperbola is along  $OY$  then the semi-axis is

$$r \cos \xi (\cos^2 \eta - \sin^2 \xi)^{\frac{1}{2}} / \sin^2 \xi.$$

Let the wave-length of the electrons be  $\lambda$  and the camera-length  $L$  with the photographic plate perpendicular to the beam, then the actual locus of the  $hk$  diffraction spot on the plate will be the above hyperbola magnified in the ratio of  $L\lambda:1$ . A typical rotation photograph would therefore consist of a large number of such hyperbolic traces, nearly all with their axes parallel to  $OX$  and their centres on the projection of the axis of rotation; furthermore, the asymptotes of all these hyperbolæ will enclose the same angle  $2\alpha$  (Fig. 11), where  $\alpha = (90^\circ - \xi)$ , i.e.,  $\alpha$  is the angle of inclination of the cross-grating to the axis of rotation. Therefore, when the rotation axis is nearly parallel to the cross-grating plane, the hyperbolæ will be acute, as in Fig. 6, and when actual parallelism occurs, i.e.,  $\xi = 90^\circ$ , the hyperbolæ will have shrunk to a set of parallel straight lines given by  $y = r \cos \eta$  with respect to  $O$  as origin and beginning at the points  $x = \pm A, = \pm r \sin \eta$ , corresponding to the apices of the hyperbolæ. Since simple curvature about an axis parallel to the cleavage plane is clearly equivalent to rotation of a plane crystal about that axis, Fig. 4 will serve to illustrate the fact that the hyperbolæ also become parallel straight lines when the axis of rotation is parallel to the cross-grating plane but not perpendicular to the beam, i.e., when  $\xi = 90^\circ$ , but  $\delta \neq 0$ .

In the general case, when  $\xi \neq 90^\circ$  and  $\delta \neq 0^\circ$ , the  $hk$  hyperbolic or elliptic locus in the  $OXY$  plane has its centre  $O'$  at the point with the co-ordinates 0 and  $-r \cos \eta \cos \delta / (\sin^2 \delta - \sin^2 \xi)$ ; the asymptotes of the hyperbolæ with respect to  $O'$  as origin are the lines,

$$y = \pm x \cos^2 \xi / (\sin^2 \xi - \sin^2 \delta);$$

and the semi-axis is of length

$$r[1 + \cos^2 \eta / (\sin^2 \delta - \sin^2 \xi)]^{\frac{1}{2}}.$$

If the locus is an ellipse the denominators of the  $x^2$  and  $y^2$  terms in equation (10) are the squares of the semi-axes, which are parallel to  $OX$  and  $OY$ .

In the case where the axis of rotation is the normal to the cross-grating,  $\xi = 0$ , and arbitrarily taking  $\eta = 90^\circ$ , the locus of the  $hk$  diffraction is

$$x^2/r^2 + y^2/(r^2/\sin^2 \delta) = 1 \quad . \quad . \quad . \quad (12)$$

The  $hk$  loci are thus all ellipses with  $O$  as centre, with the major axes in the direction  $OY$  and minor axes along  $OX$ , the semi-axes being of length  $r$  and  $r/\sin \delta$ . Such ellipses have actually been observed in the case of transmission patterns obtained from orientated polycrystalline films of cadmium iodide<sup>22</sup> and from colloidal silver.<sup>23</sup> The arcs, or rather spots, of  $hkl$  diffractions from an orientated polycrystalline specimen must lie on the corresponding  $hk$  ellipse, as in the case of a transmission pattern from an orientated colloidal graphite specimen inclined to the beam.<sup>24</sup>

The rotation of a cylindrically-curved cross-grating about any axis other than that of the curvature clearly results in the alteration in

<sup>22</sup> Kirchner, *Ergeb. exakt. Naturw.*, 1932, 11, 64.

<sup>23</sup> Finch, Quarrel and Wilman, *Trans. Faraday Soc.*, 1935, 31, Pl. 11, Fig. 27.

<sup>24</sup> Finch and Wilman, *Proc. Roy. Soc., A*, 1936, 155, Pl. 6, Fig. 2.

position and shape of the hyperbolic loci of the stationary cross-grating, so that each  $hk$  hyperbola on the photographic plate sweeps out a corresponding area throughout which diffuse diffraction effects will be recorded. Usually the crystals, e.g., of molybdenite, are at least thick enough to show more intense spots where each streak crosses the appropriate normal  $hkl$  Debye-Scherrer ring positions for the three-dimensional lattice powder-pattern; hence rotation of such a bent flake about any axis will yield well-marked arcs of the normal Debye-Scherrer ring pattern superimposed on areas of diffuse diffraction. This phenomenon has previously been observed with graphite flakes,<sup>17</sup> and we have furthermore been able to infer the existence of a very slight curvature in some otherwise apparently quite flat flakes of molybdenite and mica from their tendency to yield patterns of short arcs instead of spots in those parts of the rotation patterns corresponding to high inclination of the specimen plane to the beam. Indeed, we have in this phenomenon a delicate test for the absence or otherwise of curvature, whether macroscopic or of the lattice-type recently postulated by Lotmar.<sup>25</sup> As stated above in § 4 (*d*), the crystal yielding Fig. 7 appeared under the microscope to be quite flat in reflected light; the distinct signs of arcing visible in the case of the diffractions remote from the central spot and corresponding to large inclinations of the cleavage plane to the beam show, however, that the flake in question must have been very slightly curved.

In the above analysis the diffraction loci given by equation (10) are those of a pure cross-grating. In the case of a crystal of finite thickness the  $hkl$  diffractions must occur on these loci, because the cross-grating reciprocal lattice lines pass through the points of the normal reciprocal lattice rows of the three-dimensional lattice. The  $ool$  diffractions would appear on a pair of straight lines intersecting in the central spot. Thus in the case of these diffractions, the  $ool$  reciprocal lattice points must lie on the  $oo$  cross-grating reciprocal lattice line, and the intersection of this line with the Ewald sphere is therefore to be obtained by putting  $r = 0$  in equation (10). Hence

$$y = \pm x \cos \xi / (\sin^2 \xi - \sin^2 \delta)^{\frac{1}{2}}, \quad . \quad . \quad . \quad (13)$$

Thus when  $|\xi|$  is  $> |\delta|$ , i.e., the  $h, k$  curves are ellipses, the  $ool$  diffractions will not appear; when  $|\xi|$  is  $< |\delta|$ , i.e., the  $h, k$  curves are hyperbolæ, the  $ool$  diffractions should lie on the above lines which are parallel to the asymptotes of the  $h, k$  hyperbolæ and pass through the central spot. In view of the thinness of the crystals and their virtually infinite extent in the cleavage plane directions, it is not surprising that these diffractions do not appear in the patterns from either curved or rotated undistorted single crystals of molybdenite. As in the case of graphite, the  $ool$  diffractions are conspicuous by their absence.

Finally, we have obtained patterns of strongly-curved intense streaks of the type shown in Figs. 6 and 7 from stationary molybdenite crystals. Their origin can now be explained simply in terms of polyaxial curvature.

### Summary.

The diffraction of electrons by thin stationary and rotating molybdenite crystals has been studied. The principal facts and conclusions arrived at are as follows:—

<sup>25</sup> Lotmar, *Z. Krist.*, 1936, 91, 187.

In addition to those to be anticipated from the known structure, many anomalous diffractions have been recorded and explained in terms of the lattice limitation theory, as first applied to the graphite spectra.

Single crystals of only a few lattice layers in thickness, some free from distortion and others exhibiting only simple uniaxial curvature, have been obtained and have yielded on rotation the two-dimensional cross-grating effect of continuous diffraction lines. It has been shown that such lines, and tolerance effects in general, decrease in intensity with increasing crystal thickness. Such tolerance effects have also been recorded with mica.

As with X-rays, the axial ratio of molybdenite has been found to be 3.90, from which it is concluded that  $c$  is independent of crystal thickness.

The general theory of the loci of the diffractions from rotating undistorted and from stationary curved molybdenite crystals has been developed and shown to be in agreement with experiment.

We wish to thank Messrs. Ferranti Ltd. for apparatus and Viscount Wakefield for a scholarship during the tenure of which this work was carried out.

## THE REFRACTIVE INDEX OF DEUTERIUM.

BY W. J. C. ORR.

*Received 5th August, 1936.*

A property of deuterium which has so far not been determined is its refractive index. The present experiments were undertaken to determine the difference in refractivity of hydrogen and deuterium at constant temperature and pressure, the gases being compared simultaneously in the gas tubes of a Rayleigh Interferometer. A further consideration was that, if there were a large difference in refractive index such measurements would offer a convenient method of analysing hydrogen-deuterium mixtures. As will appear however, the difference was very small so that with the instruments used the analytic accuracy of this method was limited to  $\pm 1.0$  per cent. D.

### Apparatus.

The apparatus employed is shown diagrammatically in Fig. 1. The portion from A to F was made in duplicate and the two pieces coupled together so that the hydrogen liberated in one electrolytic cell and the deuterium in the other underwent identical treatments before entering the opposite sides of the Interferometer gas tubes at G and G'. The U-shaped cells, B, were narrowed at the bend to permit as much electrolyte as possible being electrolysed, and were fitted with platinum electrodes of  $\frac{1}{4}$  sq. cm. area, the cathodes being attached to stout platinum wires, sealed in ground glass joints. The tubes D, in which traces of oxygen were combined with hydrogen were of pyrex glass and were filled with platinised asbestos and electrically heated so that a temperature of 250-300° C. was maintained inside. The traps, C, were cooled in liquid air and those at E, by ether-CO<sub>2</sub> mixtures. In order that the gases might

be at room temperature when entering the gas tubes, spirals immersed in water, were placed at F. The two streams leaving the gas tubes were led to the opposite limbs of a mercury manometer, H, by which any difference in their pressure was immediately detected, the hydrogen then passing into the atmosphere through the constriction, J, which just touched

a mercury surface, while the deuterium passed to the CuO tube, L, which was kept at 500° C. by an electric furnace. The heavy water so produced was frozen out in the U-tube, M, cooled in an ether-CO<sub>2</sub> mixture and so recovered. The volume of each side of the apparatus from C to H was approximately 300 c.c.

### Experimental and Results.

The cells, filled first of all with ordinary water to which a little NaOH had been added, were connected in series and electrolysed at a current of 1 amp. for 6 hours. The heating coils at C, were not put on till after 3 or 4 hours so that the apparatus was filled with hydrogen without risk of explosion. During this run the zero reading on the interferometer with ordinary hydrogen in both sides of the gas tubes was determined, while in addition, it was ascertained that no leakage took place through the rubber tubing connecting the gas tubes to the apparatus and also, it was found that a correct reading of the Interferometer could be made while the gases were streaming through the tubes.

A 3*N* NaOH solution in 99.1 per cent. D<sub>2</sub>O was now placed in one of the cells and electrolysis with a current density of 0.6-1.0 amps. commenced. The following tables show the course of the readings as the experiment progressed.

(1) 3 c.c. DOD used.

Hours	0	3	4	5	1.0 c.c. DOD added	9
Drum divisions	0	22.8	24.8	27.0		27.0

(2) 2.2 c.c. DOD were then added to the alkali left after the above experiment and the following readings were obtained :—

Hours . . .	3	4	6	10	16	20	22
Drum divisions .	22.8	30.0	34.5	35.0	35.0	35.0	35.0

It is evident that all the initial  $H_2$  must be swept out after 19 hours evolution of  $D_2$  at a rate of 250 c.c per hour. Furthermore it is easily calculable from the volumes of the solutions and the known original D concentration, assuming as low a separation factor as 4, that after 19 hours electrolysis at least 99.9 per cent.  $D_2$  is being liberated. It may thus be concluded that the final reading represents the fringe displacement (given in drum divisions corresponding to pure  $D_2$ ). As a check the D concentration of the liquid left in the cell was analysed by density measurements and found to be  $99.9 \pm 0.2$  per cent. D.

The difference between the refractive indices of hydrogen and deuterium ( $\Delta\mu$ ) corresponding to an interferometric shift of 35.0 drum divisions is given by the formula :

$$\Delta\mu = \frac{N\lambda}{L} \times 10^{-8},$$

where  $N$  is the number of fringes corresponding to a shift of 35.0, when a monochromatic light source of wavelength,  $\lambda$  Å. is used ; and  $L$  is the length of the gas tubes, *viz.*, 75 cms. The correction which, in general, would be applied to this formula to take account of dispersion is completely negligible in this case where a shift of less than two fringes is involved.

The calibration of the drum reading was made using the wave-length 5462 Å., suitably filtered from a mercury arc source. The following readings were obtained for consecutive fringes :—

	934.0	948.2	962.1	976.5	991.1
Difference	14.2	13.9	14.4	14.6	
Average difference = 14.2 (5).					

Hence

$$N = \frac{35.0}{14.25} \therefore \Delta\mu = \frac{35.0}{14.25} \times \frac{5462}{75} \times 10^{-8} = (179 \pm 2) \times 10^{-8}.$$

From the design of the instrument a shift in the direction observed, indicated that deuterium had a smaller refractive index than hydrogen. The refractive index of  $H_2$  at  $\lambda$  5462, given by the Int. Crit. Tables is 1.00013966 (273 Å., 760 mm.).

Hence the refractive index of deuterium under the same conditions is 1.0001378(7).

### Summary.

The difference in the refractive indices of hydrogen and deuterium have been determined, using a Rayleigh Gas Interferometer. Assuming the value 1.00013966 for hydrogen at  $\lambda$  5462 the refractive index of deuterium is found to be 1.0001378(7).

I wish to thank Dr. J. A. V. Butler for suggesting this investigation and for his encouragement during the course of the work. I have also to express my gratitude to the Carnegie University Trust for a Scholarship, to the Moray Fund for a grant for the purchase of heavy water, and to Messrs. Imperial Chemical Industries for a grant by which the Interferometer was purchased.

## DISCONTINUITIES IN THE SORPTION PROCESS.

BY A. G. FOSTER.

*Received 5th August, 1936.*

It has been shown by Burrage<sup>1</sup> that when a silica gel containing adsorbed carbon tetrachloride vapour is heated to about 100° C., a chemical reaction occurs which results in the removal of some of the residual water of the gel. The action is presumably similar to that which is known to take place on moist charcoal,

and the removal of water is accompanied by a marked change in the shape of the sorption isothermals. Those determined on a gel which has not been subjected to any "flushing out" treatment are of normal type and show no discontinuities,<sup>2</sup> whilst those determined after treatment, the gel being completely evacuated and recharged, show a definite step-like structure, in which the pressure remains constant over a certain range of concentration and then falls abruptly to a lower value, also remaining constant for a time. Similar curves have been obtained by Burrage,<sup>3</sup> using the dynamic retentivity method, without any preliminary treatment of the gel.

During the examination of a silica gel by the dynamic retentivity method discontinuities were also observed by the author, but subsequent examination by a static method not only failed to reveal any regular discontinuities, but showed also that the true shape of the curve was considerably different from that determined by the air-stream (dynamic) method. Isothermals of several alcohols on this gel have been described previously by the author.<sup>4</sup> All show a small hysteresis loop (just before the saturation point is reached), in the "descending" branch of which, slight discontinuities have been found. At lower concentrations however, a most careful examination of all the isothermals failed to reveal any marked discontinuities. The same behaviour has been found in the present work with carbon tetrachloride, on the same gel, since the isothermals show a few breaks in the hysteresis

<sup>1</sup> Burrage, *J. Physic. Chem.*, 1933, **37**, 735.

area, but none over the pressure range investigated by Burrage. The essential shape remains unaltered after the most drastic flushing out treatment, and even after evacuating the gel at  $800^{\circ}\text{C}$ .

### I. Experiments by Static Vacuum Method.

The static vacuum technique employed was identical with that described by Burrage,<sup>1</sup> and subsequently used by the author,<sup>4</sup> for the deter-

FIG. 1.— $\text{CCl}_4$  on Silica Gel B. Hysteresis Loop.

mination of isothermals of the alcohols on silica gels, one of which, "gel B," has been used in the first series of the present experiments. A sample weighing about 5 gms. was evacuated at  $150^{\circ}\text{C}$ ., and a few sorption points were determined by direct weighing, after charging to a known pressure with carbon tetrachloride vapour. The desorption curve was then investigated in detail by the "pressure change" method. From  $q = 498$  mg. gm. to  $q = 360$  mg. gm. a total of 34 points was determined, with an average separation of 3.5 mg. gm. The upper part of the curve, shown in Fig. 1, revealed a few definite breaks, but the lower portion showed none, although a few of the points were irregular. The gel was then heated to about  $100^{\circ}\text{C}$ ., with a moderate pressure of carbon tetrachloride vapour, for several hours, but after evacuation and recharging, the isothermal remained unaltered by this "flushing out" treatment.

A second experiment was carried out a year later, using a fresh sample of gel which was flushed out twice at  $80^{\circ}\text{C}$ ., and evacuated at  $150^{\circ}\text{C}$  before determining the isothermal. This showed two very definite breaks

FIG. 2.— $\text{CCl}_4$  on Silica Gel B.

in the high pressure region, Fig. 2,—one at 26.2 mm., where three points

were obtained between  $q = 438$  and  $q = 421$ ; and another at 23.6 mm., which was less sharply defined. The original experiment, Fig. 1, gave breaks at 27.2, 26.2 and 23.6 mm. Further examination of the isothermal down to a pressure of 4 mm., gave no indication of any discontinuities although 100 points were determined. The gel, containing about 140 mg. gm. of adsorbed carbon tetrachloride, was then heated for several hours at 120° C., evacuated and recharged. The isothermal was then examined in detail from 17 mm. down to 1.8 mm. and showed a number of rather irregular discontinuities. A portion of this curve is shown in Fig. 3. The sudden fall in pressure from 2.24 mm. to 2.0 occurred after the gel had been left overnight. The longest break is about 4 mg. gm., which is less than the average values found by Burrage.

The gel, which now contained 76 mg. gm. of adsorbed carbon tetrachloride, was heated to 250° C. A considerable pressure was generated, sufficient to blow out the barrel of the container tap, indicating that a reaction was taking place between the adsorbed vapour and the residual water of the gel. The treatment was continued for 12 hours and the gel then evacuated at 150° C. before the third run was begun. This desorption curve showed breaks at 27.1 mm., and 26.1 mm., but at lower pressures the discontinuities were no more definite than before. The gel was flushed

FIG. 3.— $\text{CCl}_4$  on Silica Gel B.

out again, evacuated at 400° C., and a fourth isothermal determined, which showed breaks at 27.3 and 26.7 mm. The "ascending" branch of the hysteresis loop was also examined this time.

Finally, the gel was evacuated for a few hours at a temperature of 800° C. and a fifth curve determined. This is shown in Fig. 2, curve 2, and although the isothermal has shifted back towards the pressure axis and falls more steeply, there is no fundamental difference in shape, and the hysteresis phenomena still persist. The final evacuation of the gel showed that the zero weight had diminished by 5.4 per cent., and the data for this isothermal have been calculated from the final weight of the gel, taking into account this loss of water during flushing out and evacuation.

The second series of experiments was carried out with a sample of gel from the batch used in the work of Allmand and Burrage,<sup>8</sup> and on which the step-like discontinuities were subsequently found by Burrage.<sup>8</sup> An isothermal was first determined on a sample of gel weighing about 2 gms., evacuated at 110° C., the temperature used by Burrage. This gave the isothermal shown in Fig. 4, curve 1, which although irregular, shows no definite breaks, and is similar to that determined by Allmand and Burrage.<sup>8</sup> The gel, containing about 100 mg. gm. adsorbed vapour, was heated to 60° C. for 8 hours, evacuated and recharged. An examination of the isothermal between 3.2 and 2.5 mm. gave no very definite breaks. The

gel was then heated to 100° C. for three hours, also without effect. A third "flushing out" treatment, at 120° C. for 3 hours, also failed to reveal any discontinuities and the position of the isothermal remained unaltered. A repetition of this treatment, however, produced a remarkable change in the shape of the isothermal, the result being shown in Fig. 4, curve 2. The pressure fell from 8.9 mm. at  $q = 217$  to 0.4 mm. at  $q = 201$ . Below this concentration the pressures were too small to measure accurately on the mercury manometer. The gel was charged again to a higher pressure and a second desorption curve obtained which was almost identical with the first. The gel, containing about 200 mg. gm. of carbon tetrachloride (at a pressure of 1 mm. at 25° C.) was heated to 150° C. for 1 hour. A considerable amount of the adsorbed vapour condensed out on the cooler portion of the gel container, near the tap and was pumped away before raising the temperature to 250° C. At this temperature a pressure greater than one atmosphere was generated inside the container and the tap was again blown out. The temperature was raised to 400° C. after further

FIG. 4.— $\text{CCl}_4$  on Silica Gel A.

evacuation, but a pressure was still developing inside the container, presumably due to the reaction between carbon tetrachloride and the structural water of the gel, since fumes of hydrogen chloride were observed. This drastic treatment caused a considerable decrease in the adsorptive power of the gel, the final isothermal, Fig. 4, curve 3, rising almost vertically towards saturation between 40 and 45 mg. gm.

Another experiment was carried out using a larger amount of gel, about 6 gms., which was evacuated at 110° C. and flushed out at 60° C. for 4 hours. An examination of the isothermal between 4.0 mm. and 2.5 mm. gave a curve which, although discontinuous, was also exceedingly irregular. The gel was next flushed out at about 110° C. and a second isothermal determined which is shown in Fig. 4, curve 4. The discontinuities were less irregular than before, but no definite breaks were found. The top portion of the isothermal is of interest as it appears to represent a stage intermediate between curves 2 and 3 although the middle part still resembles curve 1.

A final experiment with another portion of the gel was performed in order to study the effect of heat treatment alone, without any "flushing out" treatment. 5 gms., evacuated at  $150^{\circ}\text{C}$ ., decreased in weight by 3 per cent. after evacuation at  $400^{\circ}\text{C}$ . The isothermal shown in Fig. 4, curve 5, has no very definite breaks.

At one point the gel was heated to  $70^{\circ}\text{C}$ . for four hours before resuming the pressure measurements at  $25^{\circ}\text{C}$ ., but no increase in pressure occurred. After the last point had been determined, at 5.34 mm. pressure, the container was heated to  $120^{\circ}\text{C}$ . for 2 hours and then opened to the manometer after reducing the temperature to  $25^{\circ}\text{C}$ . The pressure had risen to nearly 15 mm. On opening the dead space to a freezing bulb immersed in liquid air, the pressure fell to zero, but with the freezer at  $-126^{\circ}\text{C}$ . (immersed in melting methyl cyclohexane) a pressure of 1.3 mm. was recorded; which may denote the presence of either  $\text{CO}_2$  or  $\text{HCl}$ . After a final evacuation at  $150^{\circ}\text{C}$ . the gel retained 8.4 mg. gm. of carbon tetrachloride.

FIG. 5.—Carbon tetrachloride on Silica Gel.  
Retentivity method.

### Discussion.

The isothermals of carbon tetrachloride on "gel B" are similar in shape to those of the aliphatic alcohols<sup>5</sup> except at low pressures. The amounts of methyl and butyl alcohol taken up at saturation are 300 and 290 mg./gm. respectively, corresponding to 0.380 and 0.370 c.c./gm. The figures for carbon tetrachloride are 528 mg./gm., or 0.330 c.c./gm. The hysteresis loop extends over a range of about 0.056 c.c./gm. which is greater than the highest value found for the alcohols, 0.038 c.c./gm. It is interesting to note that with ethyl alcohol<sup>4</sup> and isopropyl alcohol,<sup>5</sup> discontinuities were also observed in the descending branch of the hysteresis loop. With carbon tetrachloride, the main break occurs at 26.2 mm., which corresponds to a capillary radius of 13.4 Å., calculated according to the Kelvin equation. The values calculated from the alcohol isothermals lay between 14 and 16 Å.

It has previously been shown by the author that the hysteresis phenomena observed with ethyl alcohol on this gel remains unaltered even after the most drastic flushing out treatment and after evacuation at  $350^{\circ}\text{C}$ . instead of the usual temperature of  $150^{\circ}\text{C}$ . The present series of experiments with carbon tetrachloride on the same gel confirms this result and it has now been shown that the hysteresis phenomena persist even after evacuating the gel at  $800^{\circ}\text{C}$ .

In the low pressure region the isothermals of carbon tetrachloride differ considerably from those of the alcohols. At a relative pressure of 0.01, the gel takes up 92 mg./gm. of methyl and 177 mg./gm. of butyl

<sup>5</sup> Foster, *Proc. Roy. Soc., A*, 1935, **150**, 77.

alcohol; these amounts correspond to 0.0028 and 0.0024 gm. mol./gm. respectively. At the same relative pressure only 70 mg./gm. of carbon tetrachloride are held, which represents 0.0004 gm. mol. or only one-sixth the number of molecules.

The other sample of silica gel gives irregular isothermals before it is subjected to any flushing out treatment, and the isothermal shown in Fig. 4, curve 1, is similar to that determined some years previously by Allmand and Burrage<sup>2</sup> under similar conditions. In the present investigation mild flushing out treatment as employed by Burrage<sup>1</sup> has little effect either upon the position or the shape of the isothermal, but the final result of drastic flushing out treatment is remarkable, giving the isothermal shown in Fig. 4, curve 2. The step-like breaks observed by Burrage, also shown in this diagram, curve 6, appear to represent some intermediate stage in the transition, whilst the final curve resembles the isothermals determined by McBain<sup>6</sup> on highly purified sugar charcoals, which are regarded by him as the "ideal type," to which all isothermals should approximate when impurities are eliminated. At a relative pressure of 0.01 the gel initially takes up about 70 mg. gm. or 0.0004 gm. mol, and is saturated at about 200 mg. gm. After the drastic flushing out treatment, which does not cause any increase in the saturation volume, 200 mg. gm. or 0.0013 gm. mol is held at a relative pressure lower than 0.01, so that the actual amount of carbon tetrachloride so held has increased threefold, and represents 76 per cent. of the total sorption. Comparing the pressures developed when 200 mg. gm. are adsorbed, it is found that the initial pressure of 10 mm. before flushing out, fall to 0.2 mm.—corresponding to an increase in the adsorption potential from 800 cal. to 4000 cal./mol.

The isothermal of ethyl alcohol on the gel used in these experiments is similar to that described on "gel A," one of the two samples previously examined by the author, and shows that at a relative pressure of 0.01 the gel takes up 104 mg. gm. or 0.0023 gm. mols. This represents 60 per cent. of the total sorption so that the isothermal already approximates to the ideal type. It is further important to note that these alcohol isothermals do not alter in shape after drastic flushing out treatment.<sup>4</sup>

Previous work on ferric oxide gel<sup>7</sup> indicated that the formation of the unimolecular layer was practically complete at a relative pressure of 0.01 and a rough estimate of the surface area of the gel was made by assuming that the alcohol molecules occupied an area of 20.5 Å<sup>2</sup> each. This is a minimum value which will only be attained if the adsorbed molecules are oriented with the hydrocarbon chain normal to the surface. A similar calculation from the above data for ethyl alcohol on silica gel gives the value  $2.86 \times 10^6$  cm.<sup>2</sup> for the surface per gram.

It is reasonable to suppose that the 200 mg. gm. of carbon tetrachloride, which is so firmly held after the flushing out treatment, also represents a close-packed unimolecular layer. The diameter of the adsorbed molecule is almost exactly 6 Å and on account of its symmetrical nature it is unnecessary to make any assumptions as to its orientation. If the sectional area be taken as 36 Å<sup>2</sup> the surface area of the gel per gram is found to be  $2.84 \times 10^6$  cm.<sup>2</sup>—a value identical with that calculated from the alcohol isothermal.

<sup>6</sup> McBain, *Sorption of Gases and Vapours by Solids*.

<sup>7</sup> Foster, *Proc. Roy. Soc., A*, 1934, 147, 128.

This shows that the carbon tetrachloride, which is strongly adsorbed on the flushed out gel, covers approximately the same surface area as is occupied by ethyl alcohol on the untreated gel, and since there is no change in the total adsorptive capacity, it appears that the only result of flushing out has been to alter the nature of the surface on which the sorption process occurs.

The residual water content of silica gels after evacuation at about 200° C. is of the order 5 per cent.; the removal of more water causes a decrease in activity, and the last traces can be removed only by prolonged treating at about 1000° C., which breaks down the gel structure. Little is known of the manner in which this residual water is held,\* but the vapour pressure at 200° C. is less than  $10^{-4}$  mm. Hg. during the final stages of evacuation, and there is no evidence that this water can be displaced by other adsorbed substances at ordinary temperatures. During the flushing out treatment, however, some water must evidently react with carbon tetrachloride.

After the removal of this residual water, together with the products of hydrolysis, carbon tetrachloride is able to become more firmly attached to the gel surface. It is important to note that removal of water by heat treatment alone, in vacuum, does not suffice. This is illustrated by Fig. 4, curve 5, which shows the isothermal obtained with a sample of gel initially evacuated at 150° C., then further evacuated at 400° C. The gel had then lost 3 per cent. or 30 mg./gm. of water, but subsequently failed to show any increase in the amount of carbon tetrachloride taken up at low pressures. A rough calculation shows that the area occupied by the removed water is able to accommodate at least 70 mg./gm. of carbon tetrachloride.

The essential change in the surface must therefore occur during the chemical reaction between adsorbed water and carbon tetrachloride. The process cannot be regarded as an "activated" adsorption, taking place when the temperature is raised, because the "flushing out" is performed when comparatively little carbon tetrachloride is present; the main bulk is added later at room temperature, after further evacuation, and is then strongly adsorbed. Fig. 4, curve 6, shows that removal of still more water from the gel, by further heating with adsorbed carbon tetrachloride, results in greatly diminished activity, although the isothermal retains its characteristic shape.

## II. Experiments by the Dynamic Retentivity Method.

An extensive series of experiments was carried out using the improved air-stream technique described by Burrage.<sup>3</sup> Most of the systems investigated have now been examined by the more accurate static vacuum method, and the few examples given below will serve to illustrate the unreliability of the retentivity method.

### i. Carbon Tetrachloride on Silica Gel.

The retentivity method gave very definite breaks similar to those described by Burrage.<sup>3</sup> Fig. 5, curve 1, represents the results obtained with about 3 gms. of gel and an air stream of 400 c.c./min. Curve 2 was

\* The residual water must be held partly on the surface and partly "locked up" in the interior of the gel. The latter may be present as silicic acid complexes whilst the former may exist in the form of hydroxyl groups attached to the silica atoms of the  $\text{SiO}_2$  lattice, as suggested by Rideal (*Trans. Faraday Soc.*, 1936, **32**, 4).

obtained on the same sample three weeks later using a 200 c.c./min. rate. Although there is a horizontal shift away from the p. axis of about 10

FIG. 6.—Carbon tetrachloride on Silica Gels.

mg./gm., the steps occur at very nearly the same pressures as before. The gel used here was a sample from the same batch as "Gel A," previously described by the author<sup>4</sup> and has similar characteristics to that used by Burrage.

Isothermals were also determined on another sample, "Gel B," also described previously.<sup>4</sup> In Fig. 6 the curve obtained by the static vacuum method is compared with the smoothed out retentivity curve (drawn through the middle point of all steps where present). The latter

is evidently only a rough approximation to the true isothermal.

## ii. Ethyl Alcohol on Silica Gel.

An account of an investigation of this system by the static vacuum method has already been published.<sup>4</sup> Below about 5 mm. pressure the retentivity method gave remarkable curves showing a regular step-like structure similar to the carbon tetrachloride isothermals. Two samples of gel were investigated and the pressures at which the breaks occurred were in many cases identical—Fig. 7. The average length of the steps is 2.5 mg./gm., but in both investigations by the static method, points were obtained less than 0.5 mg. apart, without any signs of horizontal breaks, even after drastic flushing out treatment, including refluxing the gel with ethyl alcohol for several hours before evacuation.

Fig. 7.—Ethyl alcohol on Silica Gels.

Fig. 8 shows the complete

isothermals obtained by the different methods. The curves for "gel B" coincide over the first 20 mg./gm. of the desorption process, after which the static curve falls more rapidly. With "gel A" the agreement is better, showing that when applied to isothermals of normal type, the dynamic method gives a fair approximation to the true isothermal, whereas with isothermals of abnormal type the results obtained over the middle range of the sorption process are in error.

### iii. Water on Silica Gel.

This system provides the most striking example of the failure of the dynamic retentivity method. The extensive examination of water isothermals on silica gel at 60° C. and 70° C. carried out by Lambert and Foster<sup>8</sup> using a static vacuum method, failed to reveal any discontinuities, although horizontal breaks had been reported by Allmand and Burrage<sup>9</sup> using the retentivity method at 25° C. The sorption of water by two samples of silica gel has now been examined in detail by both methods at 25° C. Fig. 9 shows the results obtained with "gel A." The retentivity curve is similar to that described by Allmand and Burrage, whilst the static curve resembles those obtained by Lambert and Foster. On gel B, the two curves follow one another closely from saturation down to  $q = 180$ , after which the retentivity curve is distorted, Fig. 10. Here the static method shows that between  $q = 210$  and 280 the pressure changes only from 8.0 to 8.3 mm., but there is no evidence of any abrupt pressure changes.

### Discussion.

The results obtained with ethyl alcohol on silica gel "A" (Fig. 8) show that when the isothermal is of normal type, the pressure falling steeply with concentration until quite low values are reached, the retentivity method gives a fair approximation to the true isothermal determined by the static vacuum technique. The latter, however, gives no indication of any step-like discontinuities.

The data for the other systems, which give abnormal isothermals, in which the pressure falls slowly over

FIG. 8.—Ethyl alcohol on Silica Gels.

FIG. 9.—Water on Silica Gel A.

<sup>8</sup> Lambert and Foster, *Proc. Roy. Soc., A*, 1931, 134, 246.

<sup>9</sup> Burrage, *J. Physic. Chem.*, 1930, 34, 2202.

FIG. 10.—Water on Silica Gel B.

FIG. 11.

the middle concentration range, show that the retentivity method breaks down. The agreement is reasonably good at the beginning of the desorption process, but after the middle of the flat portion of the isothermal has been reached, the pressures on the retentivity curve remain higher than those at corresponding points on the true isothermal, whilst the final drop in pressure occurs at a lower concentration and is more abrupt. The derived isothermal thus suffers a maximum distortion in the middle concentration range, which makes it impossible to apply any simple correction to obtain the true curve—such as that suggested in the modified retentivity technique.<sup>3</sup>

A typical retentivity curve, obtained by plotting the weight of charged gel against the amount of air passed, is shown in Fig. 11. This appears to consist quite definitely of a series of linear portions of gradually diminishing slope, corresponding to horizontal breaks in the pressure concentration curve, since the rate of loss  $dq/dv$  is assumed to be proportional to the pressure. A close examination of the actual loss of weight between consecutive readings shows very large variations from the mean value.

Curve.	Loss of Weight. (mg./gm.).	Mean Value.	Maximum Deviation from Mean.
I.	82, 78, 74, 80, 84	79.6	+ 4.4 to - 5.6
II.	68, 78, 68, 70, 66, 74, 76, 78	73	+ 5 to - 7
III.	66, 66, 66, 66, 62, 64, 68, 68, 56, 74	65.6	+ 8.4 to - 9.6

It is evident that a method which gives results of this nature cannot follow small changes of pressure with any degree of accuracy and probably merely shows the average value of the pressure over a fairly wide concentration range.

### Summary.

I. Isothermals of carbon tetrachloride on two samples of silica gel have been determined at 25° C., using a static vacuum method.

II. The effect of heat treatment and flushing out has been examined, but no well-defined discontinuities have been observed under any conditions.

III. After prolonged heating at 120° C. with carbon tetrachloride, some of the residual water is removed from the gel, and a marked alteration occurs in the shape of the isothermal, resulting in greatly increased adsorption at low pressures.

IV. The dynamic retentivity method has been used to determine isothermals of water, ethyl alcohol and carbon tetrachloride on silica gel. A comparison of the results with those obtained by the static technique shows that the retentivity method is quite unreliable when applied to isothermals of abnormal type.

# ON THE STABILITY OF ABIARANA GUTTA-PERCHA LATEX.

BY F. K. DANIEL, H. FREUNDLICH AND K. SÖLLNER.

Received 7th August, 1936.

## I.

Although it has long been known that the rubber latices of different species of trees differ widely as to their stability, very little information can be found in the literature.<sup>1</sup>

We compared the properties, mainly the stability, of an Abiarana Gutta-Percha latex (*Lucuma lastiocarpa*, Family Sapotaceae, Tribe *Mimusops*) with those of the fairly well-known *Hevea brasiliensis* latex. (The *Hevea* latex we used was an ammonia preserved latex of about 35 per cent. dry rubber content.) As we had only a very small sample of about 40 c.c. of the Abiarana latex, a second small sample of the same appearance and the same properties, the origin of which was not ascertained, was also used. We have good reasons to believe that it also was an Abiarana Gutta-Percha latex. For both samples and the analysis we are greatly indebted to Mr. W. H. Stevens,<sup>2</sup> London.

TABLE I.—ANALYSIS OF SAMPLE OF ABIARANA GUTTA-PERCHA LATEX.

	Per Cent. on the Latex.
Total solids . . . . .	37.1
Crepe (by acetone, washed on rolls and dried) . . . . .	33.6
Whence total solids excess . . . . .	3.5
Diffusate (70 hours) by direct measurement . . . . .	3.4
Specific gravity . . . . .	0.984
Acetone extract of dry crepe . . . . .	2.2
Nitrogen content of dry crepe . . . . .	0.20
Gutta hydrocarbon (by difference) . . . . .	31.2
Distribution of the Nitrogen:—	
	Per Cent. on Latex.      Per Cent. on Dry Material.
Total solids . . . . .	0.33      0.89
Crepe . . . . .	0.20      0.59
Diffusate . . . . .	0.17      4.97

According to Mr. Stevens' information neither of the samples contained preservatives. Both had, when we got them, a  $p_H$  of about 5.3 and a strong smell of fermentation. They remained stable and unchanged in every respect during the many months we had them under observation. *Hevea* latex, on the other hand, coagulates within a few hours unless preservatives such as ammonia are added.

In the course of some days the Abiarana latex always creamed up, forming a very concentrated cream of about 80 per cent. above an opaque,

<sup>1</sup> Cf. for instance E. A. Hauser, *Latex*, Dresden and Leipzig, 1927.

<sup>2</sup> W. H. Stevens, *India Rubber J.*, 1935, 90, 36.

yellowish serum. On being shaken the cream disperses again completely and under the microscope only single particles in vivid Brownian movement are observed. They are perfect spheres of  $1.2\mu$  diameter.

The behaviour of the two latices towards electrolytes is even more markedly different. Hevea latex coagulates readily, forming one single lump of rubber above a clear serum; if the latex is very dilute, the rubber forms coherent strings which curdle at once on slight agitation. Abiarana latex on the other hand cannot be coagulated irreversibly by electrolytes; if they are added, the Abiarana creams up rapidly; on shaking the cream readily redisperses; thereafter creaming-up, (which takes just as long as before) and redispersion can be repeated at will.

The cause of the different behaviour of the two latices is recognized by microscopic observation; in a solution of  $p_H > 6$  both have almost exclusively single particles, and although occasionally two or more approach or even collide, they do not cohere, but either repel one another immediately or rapidly rotate together for some seconds and then suddenly separate again.

In a solution of a  $p_H$  of about 3.5 to 5, or in a solution of a  $p_H > 6$  with a suitable amount of salt, a difference becomes apparent. With the Hevea a certain fraction of the collisions leads to irreversible aggregation, *i.e.*, the particles do not separate again; their joint Brownian movement is smaller and their creaming velocity higher. On creaming-up they collide with other particles or aggregates and thus grow larger and larger in course of time. If, however, very few particles are in the liquid (*e.g.*, in 1:5000 dilution), the number of collisions may be so small that a cream is formed containing not too large aggregates. These can be dispersed in the liquid by careful agitation, but, by shaking strongly, they unite to one single lump of rubber. Hence a sharp strong movement of the liquid can produce an even stronger effect than the Brownian movement, so that the total number of collisions depends on the concentration of the latex and on the movement of the liquid. The percentage of irreversible collisions depends on the degree of discharge of the particles caused by the addition of acid or salt. It increases with increasing discharge. Thus the velocity of coagulation depends on, at least, two factors: concentration of the latex and state of discharge. If the particles are so weakly discharged that coagulation is a slow process, it may be accelerated by shaking vigorously, because this greatly increases the total number of collisions and hence the fraction of irreversible collisions too.

The Abiarana particles also, when acid or salt is added, form aggregates, depending on the concentration of the latex and the degree of discharge. The more concentrated and the more discharged, the more and the larger aggregates are formed, and, therefore, the higher is the creaming velocity. But these aggregates, or nearly all of them, are reversible, and either break up spontaneously or are dispersed by sharp agitation of the liquid, by collisions with other particles or aggregates, or by an impact with the wall. They, therefore, do not grow indefinitely in course of time, as is the case with Hevea; an equilibrium is established between association and dissociation. One fraction of collisions causes the breaking up of aggregates which have been produced by another fraction. The ratio of these two fractions determines the size and number of the aggregates. Such equilibrium conditions continue when the latex is shaken, and the redispersion of the aggregates seems to take place even more quickly than their formation, in contrast to the behaviour of the Hevea latex.

The parallelism between state of discharge, aggregation and creaming velocity is very obvious (*cf.* Table II.). A given  $p_H$  and latex concentration always involve a given distribution of the particles: a corresponding fraction of them unites to aggregates of characteristic sizes, the fraction of single particles also being characteristic.

The aggregates of Abiarana are much smaller than those of Hevea, even when the latter are observed immediately after being discharged,

TABLE II.—PARALLELISM OF DEGREE OF DISCHARGE, AGGREGATION AND CREAMING VELOCITY OF AN ABIARANA LATEX (1 : 100 DILUTED).

Acetic Acid (in Millimol).	Creaming Velocity.**	State of the Particles (Determined under the Microscope).
—	> 48 <sup>A</sup>	95 per cent. of the units * are single particles. 5 per cent. are present as aggregates. Most of them contain 2, and in a few cases 3, particles.
1.00	36 <sup>A</sup>	About 50-70 per cent. of the units are single particles. Many aggregates contain 2 and 3 particles. Few bigger aggregates are present.
1.25	4 <sup>A</sup> 30'	About 30-50 per cent. of the units are single particles. Many aggregates contain up to 12 particles, but most of them only 2-5.
1.43	3 <sup>A</sup> 20'	Only few units are present as single particles. Aggregates are formed up to 20 particles, and some even larger. Most of them, however, contain 3-9 particles.

\* Each aggregate, irrespective of its size, is counted as one unit, because otherwise the percentage of single particles would be very difficult to estimate.

\*\* The latex was discharged to a different degree by adding different amounts of acetic acid. Creaming velocity was determined as follows: the latex containing the acid was filled into normal test-tubes to a height of 2 cm. and the time was noted when the latex particles had creamed up so far that the lower 1 cm. of the liquid had become so transparent that print could be read through it. The time for complete creaming up was less characteristic because with decreasing concentration of particles the number of collisions also decreases, so that a certain percentage of unaggregated or poorly aggregated particles remains, the creaming velocity of which is small and ill-defined.

The second and third column of Table II. do not seem to agree so strictly as expected. The comparatively high percentage of single particles observed under the microscope is partly due to the difference in experimental conditions. The number of collisions which can occur in the 1 mm. cavity of the slides, is much smaller than in a layer 2 cms. high. Once the particles have come close to the cover glass they are checked in their free movement and are rarely able to aggregate. The aggregates already formed, however, collide more frequently with the wall than they do in the test tube, and therefore their chance of being broken up is bigger under the microscope than in the test tube. For these two reasons, the number of single particles and the degree of aggregation on the whole must be different under the two conditions; more single particles and less and smaller aggregates will be seen under the microscope.

because in the Abiarana latex the number of collisions resulting in aggregation is much smaller. The particles dispersed by shaking show their old vivid Brownian movement and seem identical in every respect with the original single particles. We assume that the Abiarana particles do not approach each other so closely in the aggregates as do the Hevea particles, owing to strong hydrophilic layers around them though a magnification of 1100 shows no difference in the particle distance of Hevea and Abiarana aggregates; in both the particles retain their original shape.

We shall henceforth call the irreversible aggregation of Hevea latex "coagulation," and the reversible aggregation of Abiarana latex simply "aggregation."

The particles of both Abiarana and Hevea are negatively charged and therefore the aggregation (creaming-up) also of the former mainly depends on the nature of the cations, specially their valency (*cf.* Table III.).

A concentration of mono- and divalent cations larger than that given in Table III. increases the creaming velocity. A considerably larger

TABLE III.\*—AGGREGATION VALUES (MILLIMOL/LITRE) OF AN ABIARANA LATEX (1 : 100 DILUTION).

KCl.	BaCl <sub>2</sub> .	AlCl <sub>3</sub> .	Th(NO <sub>3</sub> ) <sub>4</sub> .	CuCl <sub>2</sub> .	Acetic Acid.
100	15	0.66	0.11	2	1

\* These measurements were done in a simpler way than those in Table II. We determined the electrolyte concentration which caused the latex, diluted 100-times, to cream up within 2 hours. The test-tubes, containing latex + electrolyte in different concentrations, were stood in a row, and it was easy to fix the critical concentration which could cause a distinct change in the distribution of the particles, in the course of 2 hours, while that just below did not do so. In the experiments of Table III. creaming-up had not proceeded so far as in those of Table II.

concentration of tri- and tetravalent cations and of H<sup>+</sup>-ions diminishes the creaming velocity, because these cations are able to recharge the particles positively and thus to reduce or even to entirely prevent aggregation. The reversal of charge was proved by cataphoretic tests.

## II.

What is the cause of the different stability of Abiarana and Hevea latex? The stability of Hevea seems to be mainly determined by proteins. With Scholz<sup>3</sup> we are inclined to assume that proteins sensitise the latex and render it rather hydrophobic. Scholz has found on comparing a protein-free Hevea latex with (a) an ordinary latex, and (b) with a protein solution, that the latex behaves as if it were sensitised towards all cations except the monovalent ones.

From the behaviour of the Abiarana latex we conclude that it is most likely a protected hydrophilic system. A strongly adsorbed, hydrophilic layer round the particles prevents them from approaching each other so closely that the attracting forces become predominant. This simple assumption makes the behaviour, described above, perfectly understandable.

It also explains the fact that when migrating under the influence of an electric current, the particles of Hevea form a beautifully coherent skin on the anode, (the phenomenon which renders the "anode process" feasible), while the particles of Abiarana though they are also deposited on the anode to a certain extent, do not ever form a coherent skin, but remain separated from each other and readily redispersable.

The following experiment proves that (as in a normal protected suspension) the Abiarana particles have adsorbed a foreign substance, which is also contained in the serum. If the cream is separated from the serum and shaken up with water, the aggregates are easily redispersed and cream up again readily on adding acetic acid. If this washing process is repeated several times, the latex at last creams up rapidly without addition of acetic acid and is even partly coagulated. The Abiarana latex, then, when deprived of a protecting substance contained in the serum, behaves like Hevea latex, so that the difference in the stability of the two latices must mainly be due to the presence of a protecting substance in the Abiarana and not to other factors as, for instance, the different consistency of the particles.

This experiment proves further that the protecting substance is

\* P. Scholz, *Kautschuk*, 1928, 4, 5.

adsorbed reversibly, in a true adsorption equilibrium, a fact being by on means obvious. Consequently precise conclusions concerning the Abinarana latex in normal concentration cannot be drawn from the behaviour of single latex particles in microscopic cataphoretic measurements. For these are carried out in a latex diluted 1000-times or more. This dilution corresponds to a strong washing out. Hence distinctly less of the protecting substance, which normally determines predominantly the properties of the latex, is left adsorbed on the particles. Kemp and Twiss<sup>4</sup> have drawn the same conclusions from the results of cataphoretic measurements with Hevea latex.

Another proof of the protecting action of the reversibly adsorbed substance is the fact that the washed Abiarana latex coagulates readily on being boiled, whereas unwashed Abiarana, treated in the same way, remains stable.

That the protecting substance is actually contained in the serum can easily be shown by the fact that if a sufficient amount of Abiarana serum is added to Hevea latex, the mixture is stable like the Abiarana latex itself; on adding acetic acid it does not coagulate, but only aggregates and creams up. A mixture of the whole Abiarana latex plus Hevea latex behaves of course in the same way.<sup>2</sup>

A rough quantitative investigation shows that one part of Abiarana latex completely protects one part of Hevea, if both are in their original concentration (about 35 per cent.). If diluted, less Abiarana is required e.g., one part of Abiarana diluted 1 : 50 protects three parts of Hevea of the same concentration.

A mixture of Hevea latex with a sufficient amount of Abiarana latex or serum is, like pure Abiarana, stable on being boiled, unless it has been washed beforehand. On being washed, as described above, the mixture behaves similarly to Abiarana latex, the only difference being that less washing is necessary to remove so much protecting substance as to effect coagulation. After washing, the mixture coagulates in just the same way as does pure Hevea.

### III.

We tried to find out the chemical nature of the protecting substance contained in Abiarana latex.

Since the charge of its particles can easily be reversed by  $H^+$  -ions, even after the latex has been dialysed, one could assume an ampholytic substance of the protein type to be the responsible factor. It should, it is true, be a protein, which is much more hydrophilic than the protein which determines the behaviour of Hevea latex.

The products of splitting proteins are usually more hydrophilic than the proteins themselves. Hence we investigated the reactions of Abiarana latex towards several specific reagents for proteins and the products of splitting them. In Table IV. the behaviour of Abiarana, Hevea and peptone (BDH products) are compared.

The table reveals a marked resemblance of the reactions of Abiarana with those of peptone. Several other protein products also, not mentioned in the table, such as lysalbinic acid, etc., show similar reactions. We therefore tested, whether Hevea latex could be stabilised by protein products, as it is by Abiarana serum. No protecting action was observed, with protalbinic acid, lysalbinic acid, peptone, or with any of the many

<sup>4</sup> I. Kemp and D. F. Twiss, *Trans. Faraday Soc.*, 1936, **32**, 890.

\* Reaction only takes place in neutral or acid solution, in which Hevea is coagulated in any case.

amino acids tested in many different concentrations and after leaving them in contact with the Hevea particles for shorter and longer periods; in all cases Hevea coagulated readily on addition of acetic acid. None of these substances has a stabilising action similar to that of the substance contained in Abiarana, and, therefore, none of them is probably of a similar chemical nature.

Though these experiments are incomplete, we consider it unlikely that any protein disruption products are the cause, for a second reason: On dialysing Abiarana serum through a collodion membrane the substance causing a positive biuret reaction<sup>5</sup> (see Table IV.) passes through the membrane, whereas the unknown protecting molecules were unable to do so. We could not protect Hevea latex with the liquid outside the membrane, while it was possible to do so with the liquid inside, even after lengthy dialysis. The molecules of the protecting substance are therefore bigger than those of protein products; peptone and lysalbinic acid both pass through the membrane.

The protecting substance in Abiarana latex is probably also not a true protein, because the reactions of Abiarana for proteins are negative and proteins do not so far as has been observed up to now, give a protecting action like that of the Abiarana serum. 9 gm. of gelatin, for instance, per litre of a 3 per cent. Hevea latex does not prevent coagulation. The only difference compared with the coagulation of pure Hevea is, that the system has to be strongly shaken, but this is only due to the high "viscosity" which stops Brownian movement and thus prevents the collision of the particles.

The same applies to other hydrophilic substances, *e.g.*, starch. The coagulation of a 3 per cent. Hevea latex with 9 gm. starch per litre appears to be the same as without it.

Hence we must assume the unknown protecting substance to be of a nature distinctly different from that of the usual protecting agents.

#### IV.

The results and conclusions of this investigation agree to some extent with those of Moyer who investigated many latices of the *Euphorbia*

<sup>5</sup> Since our Abiarana latex was several months old when we got it, we are unable to decide, whether the protein degradation products found were present initially or were decomposed from proteins by later fermentation.

species. Applying the Mudd technique of the moving interface, he determined the wettability of the particles<sup>6</sup> and concluded that the particles of some latices have hydrophilic, those of others more hydrophobic surfaces. Being interested in the latices chiefly from a botanical point of view, he has so far not correlated the observed surface phenomena with the stability of the latices. But Moyer's direct experimental evidence of the widely differing surface properties, though obtained for latices different from Abiarana, enhances the probability of our assumption that the great stability of the Abiarana latex results from the very hydrophilic properties of its protecting agent.

Moyer also determined with 21 species of Euphorbia the cataphoretic mobilities, as depending on the  $p_H$ , and thus the isoelectric point of their particles.<sup>7</sup> From a comparison of these curves he concludes that some latices behave as though these particles were completely coated by proteins, others as though protected by a mixture of several proteins or by a mixture of proteins with other ampholytes. A third group of latices is found to behave as though the particles were coated by non-proteins. In spite of the fact that we do not consider (for the reason mentioned above) the cataphoretic method to be quite correct for systems protected by reversibly adsorbed substances, we believe Moyer's results to hold qualitatively. Hence we can take it from him that other stable latices protected by non-protein substances exist.

### Summary.

1. The latex of Abiarana Gutta-Percha is more stable than that of Hevea. In the absence of preservatives Abiarana latex is stable for many months, whilst Hevea coagulates readily in a few hours. On addition of electrolytes Abiarana only creams up and is readily and reversibly redispersed, Hevea is coagulated irreversibly. Under the influence of the electric current Abiarana does not form a coherent skin on the anode, Hevea does so easily.

2. The stability of Abiarana latex is due to a protecting substance reversibly adsorbed on the particles. This substance may be removed by allowing the particles to cream-up repeatedly and by separating the serum from the particles.

The serum of Abiarana (or the whole latex) added to Hevea latex strongly protects the latter and causes it to behave like Abiarana latex.

3. A similar protecting action in small concentrations cannot be produced by substances such as gelatin, peptones, lysalbinic acid, starch, etc. The chemical nature of the protecting substance could not be identified. It must have a large molecular weight, since it does not diffuse through membranes.

4. The reversible creaming-up of Abiarana latex is influenced by the cations of the electrolytes added according to their valency, in agreement with the fact that the particles are negatively charged.  $H^+$ -ion and tri- and tetravalent cations are able to reverse the electrical charge of the particles.

5. The difference in creaming velocity due to different electrolyte concentrations (*i.e.*, to different degree of discharge) seems to depend on the average size and number of aggregates of particles which are formed.

# EFFECT OF LIGHT ON THE IGNITION OF MONOSILANE-OXYGEN MIXTURES.

BY H. J. EMELÉUS AND K. STEWART.

*Received 19th August, 1936.*

The authors have shown<sup>1</sup> that in the thermal oxidation of mono-, di-, and tri-silane ignition occurs when the total pressure of the gas mixture lies between two limits. The values of these vary with temperature, the diameter of the reaction vessel, and the presence of diluent gases and inhibiting substances in a manner which characterises the reactions as branching chain processes, and in the case of monosilane the following tentative mechanism was put forward:—

The  $\text{SiH}_2$  radical and atomic oxygen are considered as starting the chains. If this is correct it should be possible to produce active centres by irradiation with light of a suitable wavelength, and thus to initiate the chains in excess of the normal number started thermally. This should cause silane-oxygen mixtures to explode at pressures outside the normal ignition range. The experiments described in this paper were performed to test this point and also, as a preliminary, to determine the conditions under which monosilane will undergo photochemical decomposition.

## Absorption Spectra of the Silicon Hydrides.

The absorption spectra of the silicon hydrides were first examined, as no data were available. The three hydrides were prepared in a state of purity by the method of Stock and Somiesky<sup>2</sup> and stored in glass reservoirs fitted with mercury valves. Photographs were taken on a Hilger small quartz spectrograph (Ilford Q plates; copper arc reference spectrum). The light source was a water-cooled hydrogen discharge tube, operated by a 5000 v. transformer, and taking a current of 0.2 amp. A plane-ended quartz absorption cell, 10 cm. long, was employed.

Monosilane at pressures up to 75 mm. proved to be completely transparent to ultra-violet light down to approximately 1850 Å., the limit of the quartz spectrograph. Disilane and trisilane both absorbed light at wavelengths greater than 1850 Å. The limits of transmission in the 10 cm. cell with varying gas pressures are tabulated below:—

<sup>1</sup> Emeléus and Stewart, *J.C.S.*, 1935, 1182; 1936, 677.

<sup>2</sup> Stock and Somiesky, *Ber.*, 1916, 49, III.

TABLE I.—LIMITS OF LIGHT ABSORPTION FOR DISILANE AND TRISILANE.

Pressure of $\text{Si}_2\text{H}_6$ mm.	12	30	65	—	—	—
Pressure of $\text{Si}_3\text{H}_8$ mm.	—	—	—	12	30	60
Limit of Absorption Å.	1980	2000	2020	2140	2170	2190

The absorption in each case was continuous, and in this respect, is similar to that of the simpler paraffins and monogermene.<sup>3, 4</sup> The absorption limits of disilane and trisilane are higher than that of ethane.<sup>5</sup>

### Mercury-Sensitised Decomposition of Monosilane.

The thermal decomposition of monosilane into silicon and hydrogen takes place at  $370\text{--}500^\circ$  and has been shown recently by Hogness, Wilson and Johnson<sup>6</sup> to be a first-order homogeneous reaction and to be inhibited by hydrogen. As would be expected from the absorption spectrum of this hydride Schwarz<sup>7</sup> obtained no decomposition on irradiating monosilane with a mercury arc, though the hydrides  $\text{Si}_2\text{H}_6$  and  $\text{Si}_3\text{H}_8$  were decomposed, giving free hydrogen and brown deposits with the empirical formulæ  $\text{SiH}_{1.3}$  and  $\text{SiH}_{1.7}$  respectively.

In preliminary experiments we confirmed Schwarz' observation on monosilane, and were also unable to obtain any measurable decomposition by using a condensed aluminium spark as the light source with times of irradiation up to sixty minutes. By making use of an arc of the discharge tube type (1000 v., 0.18 amp.), giving mercury resonance radiation, however, and by introducing a pool of mercury into the reaction vessel, a relatively rapid reaction, accompanied by an increase in pressure, took place. Free hydrogen was formed and a brown film was deposited which dissolved readily in 30 per cent. sodium hydroxide solution with evolution of hydrogen. The solid reaction product was probably a polymerised unsaturated silicon hydride, or a mixture of such a hydride with amorphous silicon.

The mercury-sensitised decomposition was investigated quantitatively by irradiating a measured pressure of monosilane in a quartz bulb containing mercury for times varying from 15 to 30 minutes. The bulb was then cooled in liquid nitrogen and the uncondensed gas pumped off through a U-tube similarly cooled to retain condensable gas from the dead space of the apparatus. Such gas was distilled back into the reaction vessel and the residual pressure measured. The non-condensable gas (hydrogen) was measured by the decrease in the total pressure after pumping. The gas which had been frozen out by liquid nitrogen was next shown to be pure monosilane by distilling it in vacuum into a small bulb containing 30 per cent. sodium hydroxide solution and fitted with a tap. This bulb was attached to the apparatus by a ground joint and was removed and shaken. The hydrogen formed in the decomposition of the residual silicon hydride was then measured by reconnecting the bulb tube, evacuating the connecting tubes, and measuring the total residual pressure. The hydrogen found was slightly less than four times the volume of the residual gas

Had higher silicon volatile hydrides been present the ratio would have been greater than four (7 : 1 for  $\text{Si}_2\text{H}_6$ ).

The final stage of the analysis consisted of removing the hydrogen, and introducing into the evacuated reaction vessel 1-2 c.c. of 30 per cent. NaOH solution, which was contained in a small dropping funnel fused to the reaction system. The pressure of hydrogen liberated by the interaction of the solid reaction product and the alkali was then measured and corrected for the vapour pressure of the alkali solution. The analytical

39.9	44.7	12.0	9.6	14.7	$\text{SiH}_{0.84}$
59.5	68.5	16.0	18.5	22.7	$\text{SiH}_{0.48}$

results from three experiments are given in Table II. All pressure measurements were made at  $15^\circ\text{C}$ ., and the arc was in each case 2 cm. from the quartz bulb.

In these experiments only a small proportion of the monosilane can be decomposed as the solid film formed in the reaction render the quartz vessel opaque to ultra-violet light. The formula of the solid hydride varies from  $\text{SiH}_{0.48}$  to  $\text{SiH}_{0.91}$  with the extent of the reaction, which indicates that it is a mixture consisting possibly of amorphous silicon and the hydride  $\text{SiH}_4$  (*cf.* Schwarz and Heinrich).<sup>7</sup>

The decomposition of silane at low pressures enabled the reaction to be carried to completion, since the amount of solid deposited was relatively small, and gave a further means of examining the products. The apparatus is shown in Fig. 1. The quartz reaction bulb A (12 cm. long, 2.5 cm. diameter) was attached by a ground joint and the pressures were measured by means of the mirror Bourdon gauge<sup>8</sup> B. Small quantities of monosilane could be admitted into A by the capillary leak C, both C and B having been previously calibrated against a McLeod gauge. The reaction vessel was irradiated with the mercury resonance arc, which was placed at 2 cm. from the surface of the bulb, containing about 1 c.c. of mercury. The increase in pressure could be followed by the mirror gauge, and it was found that the initial reaction rate was constant but that at a later stage it decreased. This retardation is believed to be due to the deposition of a very thin film of solid reaction product on the quartz. The curves in Fig. 2 illustrate the course of the reaction with time. They are very similar to curves obtained by Simmons and Beckman<sup>9</sup> for the mercury sensitised

decomposition of arsine into arsenic and hydrogen. The formula of the solid silicon hydride may be calculated from the pressure change in the reaction, and is shown in Table III.

FIG. 2.—Curves showing the rate of the mercury photo-sensitised decomposition of monosilane.

The investigation of the actual reaction mechanism would require a study of the quantum yield and of the effect of hydrogen on the reaction rate. From the point of view of the mechanism of oxidation of silane, however, the primary interest lies in the intermediate formation of radicals, since it is these which are believed to be active in initiating the chain mechanism of the oxidation.

### The Effect of Ultraviolet Light on the Ignition of Monosilane-Oxygen Mixtures.

Experiments on the thermal oxidation of monosilane<sup>1</sup> have shown that mixtures containing 50 to 90 per cent. of oxygen at total pressures between 500 and 100 mm. react explosively in the neighbourhood of 100° C. No reaction was detected with such mixtures above or below the upper and lower critical explosion limits, respectively, or below the critical temperature, which was about 84° C. for a mixture containing 30 per cent. monosilane. In the experiments described below mixtures containing 30 to 50 per cent. silane were exposed to ultraviolet light at room temperature, i.e., some 70° below the minimum temperature for their thermal ignition at

any pressure. Any reaction observed under these conditions must be due to the action of the light in producing active centres in the gas mixture.

The first series of experiments was carried out at low pressures in the apparatus shown in Fig. 1, modified by the inclusion of a second calibrated capillary for the admission of oxygen into the reaction system. Gas mixtures were made up by admitting the two gases simultaneously through their respective capillaries. The composition was varied between 30 and 50 per cent. monosilane. The light sources used were a condensed aluminium spark (10,000 v., 0.3 amp.), a hot mercury arc (110 v., 2.5 amp.), and the mercury resonance arc already described. They were operated for at least ten minutes before use and were placed 10 cms. from the quartz bulb. Each of these sources caused instantaneous ignition of gas mixtures at 15-20° containing between 30 and 50 per cent. of monosilane at pressures from 2 to 11 mm. Ignition was readily detected by a sudden movement of the light spot of the mirror gauge, and also by the appearance of a white film on the quartz bulb. It took place without a measurable time lag even when the light source was removed to a distance of 40 cms., and also when the reaction vessel was screened from direct light but received light reflected from the walls of the room. It is apparent, therefore, that the amount of light needed to produce a positive effect is exceedingly small.

When a thin film of gelatin (limit of transmission 2400 Å) was inserted between the light source and the quartz bulb ignition no longer took place when the aluminium spark was used, but either the hot or cool mercury arc caused an instantaneous explosion provided the reaction vessel contained liquid mercury. The gelatin filter removes completely all radiation of a wavelength absorbed by oxygen, and ignition by the filtered light from the mercury arcs must therefore be due to the action of mercury resonance radiation. It is generally assumed that the uncooled mercury arc gives no 2537 Å. resonance light when it has been in operation for a short time, but in the present case a very small amount of such radiation probably suffices to produce a positive effect.

With the aluminium spark as the light source it was found that insertion of a filter consisting of a 5 cm. thickness of a 5 per cent. solution of sodium chloride in distilled water stopped the reaction completely. No explosion or slow reaction took place at room temperature whatever the pressure of the gas mixture. This filter removes all wavelengths less than 2050 Å., *i.e.*, those which are absorbed by oxygen. Since monosilane has been shown to be transparent down to 1850 Å. we may conclude that absorption of light by molecular oxygen alone is able to initiate explosion. Such light produces excited oxygen molecules in the first place, but may yield oxygen atoms by a secondary process.

At higher pressures (100-500 mm.) a slow reaction was observed on irradiating silane-oxygen mixtures with the mercury resonance arc. The reaction vessel consisted of a cylindrical tube (10 cm. long, 2 cm. diameter) with a side tube which was ground at the open end. To this a quartz window was attached with wax. Monosilane-oxygen mixtures were prepared by distilling the hydride into the reaction vessel, by cooling the lower part in liquid nitrogen, and measuring its pressure on a mercury manometer. It was then frozen out again and the requisite amount of oxygen added, after which the monosilane was allowed to vaporise very slowly, and the total pressure measured. As it was desired to obtain a measurable reaction rate, instead of explosion, on illumination no mercury was placed in the reaction vessel, though a restricted supply would be furnished by the manometer. The mercury resonance arc was placed 4 cm. from the quartz window. This caused only a slight rise in temperature of the reaction vessel.

Under these conditions silane-oxygen mixtures reacted slowly with a pressure decrease, and a white deposit of silica formed on the quartz window. Some typical curves obtained by plotting the pressure decrease against time are shown in Fig. 3. In all cases there was an induction

period, which was greater the higher the initial pressure and the higher the initial oxygen concentration. In the initial stages of the reaction the curves are approximately exponential and satisfy the relationship

$$\Delta p = ke^{\phi t},$$

which is valid in the thermal oxidation of hydrocarbons and other substances. As the reaction proceeds the deposit of silica retards the reaction and prevents an exact kinetic study of the reaction being made.

In no cases were we successful in obtaining a slow reaction culminating in an explosion. If, however, the pressure of the reaction mixture was

FIG. 3.—Slow oxidation of Monosilane.

4	169	24.6
5	110	22.8

slowly reduced immediately after irradiation had been commenced an explosion took place when a certain limiting pressure was reached. Thus, for example, a 16 per cent. mixture at  $20^\circ \text{C}$ . at an initial pressure of 580 mm. exploded when the pressure was reduced to 66 mm. during irradiation. Such a mixture would not explode at any pressure if it were not irradiated; indeed, our previous observations have shown that the temperature would have to exceed  $80^\circ \text{C}$ . before ignition would take place on reducing the pressure. The effect of light is therefore to lower the ignition temperature for this mixture at a given pressure by  $60^\circ \text{C}$ .

### Discussion.

The effect of ultraviolet light on the upper critical explosion limit of monosilane-oxygen mixtures is similar to that first observed by Hinshelwood and Clusius<sup>10</sup> in the case of the lower critical oxidation limit of phosphine-oxygen mixtures and afterwards studied in greater detail by Melville,<sup>11, 12</sup> for both the upper and lower critical limits. Hinshelwood and Clusius found that when irradiated, phosphine oxygen mixtures exploded at a lower pressure than the normal critical limit, which was of the order of a few mm. It was shown that irradiation produced an active substance, and that the activity and the consequent lowering of the lower explosion limit persisted for some time after irradiation was stopped. The effective wavelengths were between 2500 and 2800 Å. Such light is not absorbed by phosphine<sup>13</sup> and it is possible that the active light was the mercury resonance line 2537 Å. Melville<sup>14</sup> proved that the lowering of the explosion limit of phosphine-oxygen mixtures by irradiation with a mercury arc was due to a change in the surface of the reaction vessel: indeed, the phenomenon could be reproduced by pretreating the walls with atomic hydrogen.

The experiments on the irradiation of silane-oxygen mixtures differ from those with phosphine in one important respect, namely, that monosilane does not absorb light of wavelength greater than 1850 Å. Accordingly the initiation of explosion by irradiation with the aluminium spark is an unambiguous case of a chain reaction initiating by exciting only the oxygen molecules. The observations are consistent with the reaction mechanism given (p. 1577), for atomic oxygen can be formed by the process

Alternately it is possible for excited molecular oxygen to initiate the oxidation of monosilane. The mechanism advanced is admittedly tentative, and the kinetic analysis of the results on the thermal oxidation<sup>1</sup> would be equally valid if the two active centres propagating the chain were  $\text{O}_2^*$  and  $\text{SiH}_2$ . We hope, however, to carry out further experiments to differentiate between the effects of molecular and atomic oxygen in initiating these reactions.

### Summary.

- (1) Monosilane, disilane, and trisilane absorb light of wavelengths < 1850, < 1980-2020, < 2140-2190 Å. respectively.
- (2) Monosilane mixed with mercury vapour is decomposed by the 2537 Å. mercury resonance line, giving hydrogen and a solid reaction product consisting of a polymerised hydride  $\text{SiH}_x$  ( $x < 0.9$ ) or a mixture of silicon and such a polymer.
- (3) Monosilane-oxygen mixtures at temperatures below the normal range for thermal ignition may be caused to explode by irradiation with light from an aluminium spark or a mercury resonance arc.
- (4) Monosilane-oxygen mixtures at pressures above the critical explosion pressure undergo a slow oxidation on exposure to the unfiltered light from a mercury resonance arc. This reaction has an induction period, and, in

## THE OXIDATION OF CARBON—PART II.

By J. D. LAMBERT.

*Received 19th August, 1936.*

Two types of process possible in the oxidation of carbon are :

(1) Direct formation of carbon dioxide by impact of oxygen molecules on a clean carbon surface.

2. Primary formation of both carbon dioxide and carbon monoxide by the breakdown of surface oxide complexes.

It was shown in a previous paper<sup>1</sup> that in the temperature range 250-500° C. pure carbon is oxidised by process (1) alone; whilst the presence of iron in the carbon blocks process (1) and oxidation proceeds exclusively by process (2). The latter reaction is complicated by a secondary conversion of carbon monoxide to carbon dioxide which masks the proportion in which the two products are initially formed and in default of information as to the constancy or simplicity of this proportion the exact mechanism of the oxidation process was obscure. Further experiments have been made in order to throw light upon this problem. The first stage was to investigate the conversion of carbon monoxide to carbon dioxide: the second stage to try to eliminate this secondary effect in the light of the information obtained.

The experimental method was that previously described<sup>1</sup> and the same apparatus and materials were used. The carbon monoxide was obtained from a cylinder, and was shown by analysis to contain not more than 3 per cent. of impurity (approximately 1 per cent. carbon dioxide, 1.5 per cent. oxygen and 0.5 per cent. nitrogen). This was less pure than the oxygen and nitrogen used, which were usually 99.5 per cent. pure, and the experimental accuracy which could be obtained when using carbon monoxide was correspondingly lower.

### The Conversion of Carbon Monoxide to Carbon Dioxide on the Carbon Surface.

The conversion of carbon monoxide to carbon dioxide was investigated on coconut charcoal, graphite, anthracite, and iron treated coconut charcoal by passing mixtures of carbon monoxide and nitrogen, carbon monoxide and oxygen, and nitrogen and oxygen over the carbon at various temperatures and analysing the products. It was found that in no case is there any conversion of carbon monoxide to carbon dioxide *except in the presence of oxygen*. The process therefore appears to be an oxidation and not, as was previously supposed, an autoxidation. The results obtained with mixtures of carbon monoxide and oxygen are shown in Table I. Comparison of the products obtained from a carbon monoxide-oxygen mixture

<sup>1</sup> Lambert, *Trans. Faraday Soc.*, 1936, **32**, 452.

with those obtained under the same conditions from a nitrogen-oxygen mixture containing the same percentage of oxygen shows clearly whether or not oxidation of carbon monoxide is taking place but is insufficiently accurate to give information about the kinetics or mechanism of the reaction. It is not possible with the experimental accuracy available to sort out the results of primary carbon oxidation, secondary oxidation of the carbon monoxide produced and primary oxidation of the carbon monoxide initially present together with the accompanying volume changes. The qualitative information which is obtained however enables several important conclusions to be drawn.

### Discussion in Relation to Previous Results.

The small temperature range over which experiments could be made on the kinetics of oxidation of each form of carbon used was arbitrarily determined by the relation between rate of reaction and the available rates of gaseous flow.<sup>1</sup> The experiments on coconut charcoal were made in the neighbourhood of 260° C., those on graphite 450° C., on anthracite

and on iron treated charcoal 380-390° C. Under these conditions graphite and coconut charcoal were oxydised to carbon dioxide, and anthracite and iron treated coconut charcoal to a mixture of carbon dioxide and carbon monoxide with the proportion of carbon dioxide increasing with the time of reaction. Table I. shows that although rapid oxidation of carbon monoxide takes place on coconut charcoal at higher temperatures there is no trace of this at 260° C. so that the assumption which was previously made that carbon dioxide is the sole primary product of reaction is justified. In the case of graphite rapid oxidation of carbon monoxide does take place at 450 °C. but the very close resemblance of the reaction kinetics with those shown by coconut charcoal, together with the fact that no trace of carbon monoxide is found in the reaction product gives some justification to the same assumption. Anthracite, as was to be expected, shows a definite though not very rapid oxidation of carbon monoxide at 387° C., which is sufficient to account for the variation in the composition of the oxidation product, and a much more rapid oxidation of carbon monoxide at higher temperatures. The iron treated charcoal shows considerable oxidation of carbon monoxide at higher temperatures but no appreciable effect at 411° C., although when oxydised at 390° C. its behaviour was similar to that of anthracite: possibly different samples vary in this respect. The oxidation of both of these latter charcoals gave an apparent course of total reaction with time approximating closely to first order.<sup>1</sup> As the conversion of carbon monoxide to carbon dioxide is an oxidation and not an autoxidation ( $2\text{CO} \rightarrow \text{CO}_2 + \text{C}$ ) as was previously assumed, the secondary process will increase the total percentage of oxygen which has reacted. The approximation to first order is, therefore, fortuitous as with increasing time of reaction a considerable proportion of the observed percentage reaction must be attributed to secondary oxidation of carbon monoxide. The rate of the primary reaction must fall off with time more rapidly than the observed rate and the primary reaction must be of an order higher than first. This is in complete accordance with the views put forward later.

### Experiments on Manganese Treated Charcoal.

General inspection of Table I. shows that at high temperatures carbon monoxide undergoes oxidation much more rapidly on coconut charcoal and on graphite than on anthracite and iron treated charcoal. It would appear that the presence of iron on the carbon inhibits the surface oxidation of carbon monoxide to a large extent. This suggested that it might be

possible to find another "promoter" which would show the same effect as iron and in addition inhibit completely the secondary carbon monoxide oxidation at a temperature when the primary combustion took place at a measurable rate; thus enabling investigation of the true composition of the primary reaction product. It was found that a sample of coconut charcoal treated with manganous chloride by a process identical to the previously described treatment with ferric chloride<sup>1</sup> fulfilled the required conditions, and experiments with this charcoal are described below.

The charcoal undergoes oxidation at roughly the same conditions of temperature and rate as anthracite and iron promoted charcoal to a mixture of carbon dioxide and carbon monoxide.

The Course of Reaction with

Time is shown by Table II. and is approximately described by a second order equation. The ratio of carbon dioxide to carbon monoxide in the product is almost constant and independent of the time of reaction.

The effect of Initial Oxygen Concentration is shown in Fig. 1. The percentage reaction in a given time decreases a little with increasing

	3.30	34.2	13.56	5.96	2.28

were all given by a single sample of charcoal and are arranged in the order in which they were obtained. At temperatures between 370° C. (the lowest temperature at which measurable oxidation took place) and 430° C. the ratio of carbon dioxide to carbon monoxide is independent of the time of reaction and approximately constant between  $\text{CO}_2/\text{CO} = 1.9 - 2.0$ . There is a tendency for the proportion of carbon dioxide to increase as the charcoal burns away: the last value of the ratio taken at 407° C. is 2.28. At temperatures above 430° C. the proportion of carbon monoxide begins to show a definite increase, partially masked by the simultaneous setting in of secondary carbon monoxide oxidation.

### Discussion.

The kinetics of the oxidation of manganese treated charcoal show a course of reaction approximating to second order, and an effect of initial oxygen concentration approximating to first order. This can be interpreted in terms of a reaction of an order between first and second with respect to oxygen and retarded by the reaction products, following an expression of the form:

$$\frac{d[\text{products}]}{dt} = \frac{k[\text{O}_2]^x}{1 + b[\text{products}]}$$

If " $x$ " has a value between one and two the retardation factor " $b$  [products]" will cause the rate to fall off more rapidly with time than it would otherwise do, thus increasing the apparent order of reaction towards two; whilst the accelerating effect of an increase of the initial oxygen concentration will be counterbalanced by an increase in  $b$  [products], diminishing the apparent order towards one. An order between first and second would be shown by a mechanism involving the breakdown of an incomplete surface oxide layer on impact of oxygen molecules from the gas. The oxide layer being incomplete, its extent will be proportional to a fractional power of the oxygen pressure and:

$$\begin{aligned} \text{Rate of reaction} &= k \times (\text{number of impacts of gaseous oxygen molecules on surface oxide layer}). \\ &= k \times [\text{O}_2] \text{ (amount of surface oxide)}. \\ &= k'[\text{O}_2][\text{O}_2]^n = k'[\text{O}_2]^{(1+n)} \end{aligned}$$

" $n$ " being a fraction less than unity.

Such a mechanism is in accordance with the views previously expressed and with the experimental results *except* in so far as Tables III. and IV. show no trace of retardation by either carbon monoxide or carbon dioxide. It is difficult to find any alternative explanation of the kinetics, and this suggests that the primary product which gives retardation is due to something other than free carbon dioxide or carbon monoxide which gradually accumulates on the surface.

It is interesting to note that the carbon suboxide described by Klemenc,<sup>2</sup> decomposes at 400° C. to give carbon monoxide and carbon dioxide in ratios varying from  $\text{CO}_2/\text{CO} = 2.12 - 1.86$  which are in striking agreement with the values given in Table V. for temperatures in this region. The proportion of carbon monoxide produced by decomposition of the suboxide increased with rise of temperature, as was found in our experiments, reaching a value of  $\text{CO}_2/\text{CO} = 1.0$  at 500° C. This cannot be compared with values in Table V., as considerable secondary oxidation of carbon monoxide had set in before this temperature, but the ratios found at 530° C. are not incompatible with a primary ratio of 1:1. There is scarcely sufficient justification for supposing that carbon suboxide itself is the primary product of oxidation of manganese treated charcoal in view of the very complex phenomena involved in its decomposition and the difficulty of predicting their influence on the kinetics of the reaction, but considerable similarity clearly exists between the two cases.

All the above considerations may be applied equally to the phenomena observed with anthracite and iron-promoted coconut charcoal if the secondary oxidation of carbon monoxide is taken into account.

### Summary.

Previous work<sup>1</sup> had shown that carbon containing iron is oxydised at 400° C. to give a mixture of carbon dioxide and carbon monoxide as primary product. The reaction mechanism is obscured by secondary conversion of carbon monoxide to carbon dioxide, which masks the ratio in which the two gases are initially formed. Further investigation has been made of this secondary process, which has been shown to be an *oxidation* occurring more rapidly on a clean carbon surface than on a carbon surface containing iron. The earlier experimental results are discussed in the light of the information obtained.

It has been found that coconut charcoal treated with manganese shows similar behaviour to iron treated charcoal on oxidation at 400° C. but *without* secondary oxidation of carbon dioxide monoxide.. The oxidation of this charcoal has been fully investigated with special reference to the composition of the product, and the reaction mechanism is discussed. It appears possible that a gaseous complex similar to carbon suboxide<sup>2</sup> is the primary product of oxidation.

The author is very grateful to Mr. C. N. Hinshelwood for his interest in the whole of this work.

## THE VAPOUR PRESSURE AND HEAT OF SUBLIMATION OF CARBON.

BY PAUL GOLDFINGER AND WILLIAM JEUNEHOMME.

*Received 5th July, 1936.*

1. The value usually accepted for the heat of sublimation (vaporisation) of carbon, corresponding to the process

$$C_{\text{diamond}} = C(^3P)_{\text{gas}} - L_C \quad . \quad . \quad . \quad (1)$$

at 0° K is  $L_C \sim 150$  kcal.<sup>1</sup> This value was obtained originally by K. Fajans<sup>2</sup> from the vapour pressure measurements of H. Kohn and M. Guckel.<sup>3</sup> Their method is, however, very indirect, and their results seemed to be in disagreement with those of other authors.<sup>4</sup> Besides, it is necessary to consider the fraction of  $C_2$  in the carbon vapour<sup>5</sup> and the data necessary to calculate the equilibrium

are very incomplete.

<sup>1</sup> E.g., R. G. W. Norrish, *Trans. Faraday Soc.*, 1934, **30**, 103.

<sup>2</sup> Z. *Elektrochemie*, 1925, **31**, 60; Z. *Physik*, 1920, **1**, 101.

<sup>3</sup> *Ibid.*, 1924, **27**, 307.

<sup>4</sup> Of the numerous references given in the International Critical Tables on the vapour pressure of carbon only three, except the work of Kohn and Guckel, concern experimental determinations: (a) Wertenstein and Jedrzejewski, *Comptes rendus*, 1923, **177**, 316; (b) A. Thiel and F. Ritter, Z. *anorg. Chemie*, 1924, **132**, 125; (c) E. Ryschkewitsch, Z. *Elektrochemie*, 1925, **31**, 54; see also A. L. Marshall and F. J. Norton, *J. Amer. Chem. Soc.*, 1933, **55**, 431.

<sup>5</sup> G. B. Kistiakowsky and W. E. Vaughan, *Physic. Rev.*, 1932, **40**, 47.

Several authors have therefore sought to obtain a more exact value of  $L_C$  from thermochemical cycles.<sup>6</sup> However, only the relation<sup>7</sup>

$$L_C = D_{CO} - 86.3 \pm 0.2 \text{ kcal. (86.3 kcal.} = 3.74 \text{ v.)} \quad (2)$$

between  $L_C$  and the energy of dissociation,  $D_{CO}$ , of the normal CO molecule to normal C and O atoms is sufficiently accurate to permit an improvement of the former value.

A few other magnitudes, related to  $D_{CO}$ , and therefore to  $L_C$ , were given recently by P. Goldfinger, W. Lasareff and B. Rosen.<sup>8</sup>

It may be useful to emphasise that older spectroscopic data on  $D_{CO}$  were rather uncertain: the value given by R. S. Mulliken for example<sup>9</sup> was obtained from "thermochemical data," i.e., probably from  $L_C$ : to use this value, as certain authors have done, to obtain  $L_C$  from  $D_{CO}$  is of course a *circulus vitiosus*.

2. Recently considerable progress has been made concerning the spectroscopic value of  $D_{CO}$ .

D. Coster and F. Brons<sup>10</sup> as well as R. Schmid and L. Gerö<sup>10</sup> have observed predissociation in  $v = 0, J = 38$  and  $v = 1, J = 18$  of the  $B^1\Sigma$  level of carbon monoxide. The asymptote of the perturbing electronic level lies according to B. Rosen<sup>11</sup> at  $11.06 \pm 0.005$  v. We have therefore

$$D_{CO} = 11.06 \pm 0.005 - E \text{ v.} \quad (3)$$

where  $E$  is the sum of the electronic activation energies of the dissociation products of the perturbing level.

Three values in agreement with equation (3) were discussed by Goldfinger, Lasareff and Rosen;<sup>8</sup>

TABLE I.—SPECTROSCOPIC VALUES OF THE DISSOCIATION ENERGY OF CARBON MONOXIDE ( $D_{CO}$ ) AND CORRESPONDING VALUES OF THE HEAT OF SUBLIMATION OF CARBON ( $L_C$ ).

	I.	II.	III.
$D_{CO}$	11.06	9.10	8.39 v.
$L_C$	168.8	123.6	107.2 kcal.

these and the corresponding values of  $L_C$  are given in Table I.

There is only one intermediate value,  $D_{CO} = 9.81$  v., but this is, according to D. Coster and F. Brons<sup>10</sup> in disagreement with the data on the  $A''\Pi$  level of CO; other intermediate values, as for example  $D_{CO} = 10.4$  v.<sup>12</sup> are in disagreement with equation (3), because there are no other electronic levels of C and O, with small activation energy, except  $^1D$  and  $^1S$ , and these were con-

sidered in Table I. in all combinations.

In a preliminary note, Goldfinger and Lasareff<sup>7</sup> have proposed the value  $D_{CO} = 11$  v., the corresponding value of  $L_C$  being in best agreement with the usually accepted data; as will be shown here, the vapour pressure curve of carbon, calculated from this value is in sufficiently

<sup>6</sup> E.g., G. B. Kistiakowsky and H. Gershinowitz, *J. Chem. Physics*, 1933, **1**, 432.

<sup>8</sup> P. Goldfinger, W. Lasareff and B. Rosen, *Comptes rendus*, 1935, **201**, 958; cf. also *Comptes rendus du 2me Congres National des Sciences*, Bruxelles, 1935.

<sup>9</sup> R. S. Mulliken, *Rev. Modern Physics*, 1932, **4**, 1.

<sup>10</sup> D. Coster and F. Brons, *Physica*, 1934, **1**, 155, 634; R. Schmid and L. Gerö, *Z. Physik*, 1935, **93**, 656; **96**, 198, 546.

<sup>11</sup> *Nature*, 1935, **136**, 226.

<sup>12</sup> R. Lessheim and H. Samuel, *ibid.*, **136**, 606.

good agreement with the data of Kohn and Guckel and the discrepancy with those of Ryschkewitsch, Wertenstein and Jedrzejewski as well as Marshall and Norton<sup>4</sup> can easily be explained.

However, from the spectroscopic standpoint, the value  $^{18}D_{CO} = 9.10$  v. first proposed by Rosen<sup>4</sup> seemed much more satisfactory. In fact, this value gives for the dissociation energy of the  $A^1\Pi$  level 4.3 v., whereas the former value would give 3.07 v.; the extrapolated value is about 4 v., vibrational levels being observed up to 2.41 v. Moreover, the missing of the higher vibrational levels of the  $B^2\Sigma$  state can only be explained if there is a perturbing level with an asymptote below 11 v. Therefore  $D_{CO} = 9.10$  v. was accepted by Goldfinger, Lasareff and Rosen,<sup>8</sup> who have shown also that different magnitudes, which are related to  $D_{CO}$  are in much better agreement with this value, than with the value  $D_{CO} = 8.39$  v. proposed by Coster and Brons and Schmid and Gerö.

The present paper was practically concluded, when Brons<sup>14</sup> published results concerning a predissociation at 9.68 v. and Schmid and Gerö<sup>15</sup> on a predissociation at 9.57 v. This is a definite argument against the value  $D_{CO} = 11.06$  v.; although the arguments of Brons as well as of Schmid and Gerö in favour of  $D_{CO} = 8.4$  v. are not considered as definite by G. Herzberg,<sup>16</sup> who also proposes  $D_{CO} = 9.1$  v. His considerations, as well as those of Goldfinger, Lasareff and Rosen<sup>8</sup> can be applied *a fortiori* to the value 6.9 v. proposed by Schmid and Gerö.<sup>15</sup>

It seemed possible to improve considerably the accuracy of the discussion, by calculating, by the methods of statistical mechanics the vapour pressure curves for the three values of  $L_C$  given in Table I. These curves are sufficiently different to make a decision between them possible even with rather rough experimental data. This would permit us then to obtain finally, by equations (2) and (3), a value of  $L_C$ , which must be exact within less than 0.5 kcal.

3. The equilibrium pressure of monatomic carbon vapour, considered as an ideal gas, in presence of solid or even liquid carbon can be calculated with an accuracy which is certainly much higher than could be obtained by any direct measurement, supposing, of course, that a decision between the three values of  $L_C$  given in Table I. is possible.

(a) The molal free energy ( $F_1^0$ ) of monatomic carbon vapour is given in the notations of F. W. Giaque<sup>17</sup> by

$$\frac{F_1^0 - E_{0,1}^0}{T} = R \log_e P_1 - 3/2 R \log_e M_1 - R \log_e Q_1 - (5/2 R \log_e T + C + R \log_e R) \quad (4)$$

where  $E_{0,1}^0$  is the zero point energy of carbon gas,  $R = 1.986$  cal. the gas constant per mole,  $C = R \log_e \frac{(2\pi k)^{3/2}}{h^3 \cdot N^{5/2}} = -16.024$  the Sackur constant and  $M = 12.00$  the atomic weight of carbon;

$$Q_1 = 9 + 5 \cdot e^{-28,800/RT} + \dots$$

<sup>18</sup> Instead of this value <sup>11</sup> Goldfinger and Lasareff<sup>7</sup> gave first  $D_{CO} = 8.79$  v., from an extrapolation of the  $A^1\Pi$  level, since the exact value of the asymptote (11.06 v.) was not then known.

<sup>16</sup> Letter to the editor of *Nature*, 1936, **137**, 620; cf. also a detailed discussion by Herzberg to be published soon. By the kindness of Professor Herzberg, we were able to see the manuscript before publication.

<sup>17</sup> *J. Amer. Chem. Soc.*, 1930, **52**, 4808.

is the partition function for the electronic levels of the carbon atom (the second term already represents only a correction of about 1 per cent. at 4000° K. and 2.5 per cent. at 5000° K., and was therefore neglected).

The right-hand side of equation (4) is simply obtained by adding the values of the function  $\frac{5}{2} R \log_e T + C + R \log_e R$ , given by Giauque (*loc. cit.*<sup>17</sup> p. 4827) the practically constant value

$$R \log_e 12.00 + R \log_e Q_1 = 11.768$$

entropy units (cal./degree).

(b) The free energy ( $F_2^0$ ) of solid graphite is given by the classical formula

$$\frac{F_2^0 - E_{0,2}}{T} = \frac{1}{T} \int_0^T c_p dT - \int_0^T \frac{c_p}{T^2} dT \quad (5)$$

where  $c_p$  is the specific heat at constant pressure. For the specific heats up to 2500° K. we have used the data of the International Critical Tables: from 298.1° to 1200° K. the formula of A. Magnus<sup>18</sup> and from 1200° to 2500° the formula of Worthing.<sup>19</sup> Above 2500° Fajans estimated  $c_p = 6.5$  cal. for solid carbon up to the melting-point, which lies at 3800° K.,<sup>20</sup> and  $c_p = 8$  cal. for liquid carbon: we used the former value from 2500° to 3800° K. and the latter value from 3800° upwards. Moreover, at these high temperatures even a considerable error in  $c_p$  does not appreciably influence the value of the vapour pressure.

Above the melting-point the gas is in equilibrium with liquid carbon: according to the Clausius-Clapeyron equation the free energy obtained from equation (5) must be corrected to give the free energy of liquid carbon  $F_1^0$ :

$$\frac{F_1^0}{T} = \frac{F_2^0}{T} + \frac{\lambda \cdot (T - 3800^\circ)}{T \cdot 3800} \quad (5a)$$

$\lambda$  the heat of fusion at 3800° is not known. Fajans<sup>2</sup> made an estimate of  $\lambda \sim 8$  kcal., on the basis of a rule for melting-points and heats of fusion analogous to Trouton's rule. According to this rule, it seems to us safer to take  $\lambda \sim 13$  kcal. although an error of 50 per cent. in  $\lambda$  introduces in the calculated equilibrium pressure only an error of about 10 to 15 per cent. between 4000 and 4500° K.

(c) The equilibrium condition is  $F_2^0 = F_1^0$  (and above the melting-point  $F_1^0 = \bar{F}_1^0$ );  $R \log_e P_1$  is given by the difference of equations (4) and (5), where  $E_{0,2} - E_{1,1} = L_C$ . Table II. gives the values of  $\log_{10} P_1$  for the three different values of  $L_C$ .

For the right value of  $L_C$  up to about 3000° K. the  $\log_{10} P_1$  values are probably accurate within about  $\pm 1$  per cent. In Table II. we have given for comparison with our values of  $(F^0 - E_0^0)/T$  for graphite those of O. Clayton and F. W. Giauque;<sup>21</sup> the slight differences seem to be within the accuracy mentioned above. A zero point entropy of graphite as suggested by A. R. Gordon<sup>22</sup> would change  $\log_{10} P_1$  by about 0.1, i.e.,  $P_1$  by about 25 per cent. for all temperatures; nevertheless, even very exact vapour pressure measurements can decide this question only if our knowledge on the equilibrium (1a) is considerably improved. Above 3000° K. the calculations become uncertain, and it is possible that an

<sup>18</sup> *Ann. Physik*, 1923, **70**, 303.

<sup>19</sup> *Physical Rev.*, 1918, **12**, 199.

<sup>20</sup> Ryschkewitsch<sup>4</sup> and H. Alterthum, W. Fehse and M. Pirani, *Z. Elektrochemie*, 1925, **31**, 313.

<sup>21</sup> *J. Amer. Chem. Soc.*, 1932, **54**, 2623.

<sup>22</sup> *J. Chem. Physics*, 1933, **1**, 308.

error is introduced which increases with temperature and reaches about 10 to 15 per cent. near 5000° K.

TABLE II.—EQUILIBRIUM PRESSURE OF MONATOMIC CARBON VAPOUR IN PRESENCE OF GRAPHITE FOR DIFFERENT VALUES OF THE HEAT OF EVAPORATION.

Temperature °K.	$\frac{F_2^\circ - E_2^\circ}{T}$		$\log_{10} P_1$ (Atmospheres).		
	Our Calculation.	Glaue and Clayton.	$L_0 = 168.8$ .	$L_0 = 123.6$ .	$L_0 = 107.2$
298.1	0.545	0.545	—	—	—
1200	3.482	3.391	—	—	—
2000	5.427	5.394	- 10.381	- 5.407	- 3.647
2500	6.424	6.411	- 6.671	- 2.692	- 1.284
3000	7.314	7.309	- 4.208	- 0.892	+ 0.281
3500	8.103	—	- 2.459	+ 0.383	+ 1.389
4000	8.81	—	- 1.19	+ 1.30	+ 2.18
4500	9.47	—	- 0.26	+ 1.97	+ 2.73
5000	10.01	—	+ 0.50	+ 2.50	+ 3.20

For the subsequent discussion it may be useful to remark that even if somewhere above 2500° K. (limit of Worthings measurements) a hitherto unknown transformation point of graphite should occur, an error of 0.3 to 0.5 units in  $\log_{10} P_1$  seems already very improbable, as can be seen by equation (5a).

(d) The equilibrium (1a) can only be evaluated very roughly, because the value of  $D_{C_2}$  is quite uncertain. The free energy  $F_2^\circ$  of  $C_2$  molecules is given by an expression of the same form as equation (4), except that here  $Q = Q_e + Q_v + Q_r$ , where  $Q_e$ ,  $Q_v$  and  $Q_r$  are the partition functions of the electronic, vibrational, and rotational energy of the  $C_2$  molecule.

Since the calculation cannot be done exactly, it seems sufficient to consider only the lowest  $^3\Pi$  state of multiplicity 6 and use for  $Q_v$  the Einstein formula  $Q_v = \frac{I}{1 - e^{\theta/T}}$  with  $\theta = 2333^\circ$  and  $^{23} Q_r = \frac{8\pi^2 \cdot I k T}{2h^2}$  with  $I = 34.07 \times 10^{-40}$  c.g.s. The equilibrium condition is  $2F_1^\circ = F_2^\circ$ , this gives

$$-R \log_e K = -R \log_e \frac{P_2}{P_1^2} = \frac{3}{2} R \log_e M_1 + \left( \frac{5}{2} R \log_e T + C + R \log_e R \right) \\ - \frac{3}{2} R \log_e 2 + R \log_e 9 - R \log_e Q_v - R \log_e Q_r - \frac{2E_{0,1}^\circ - E_{0,2}^\circ}{T},$$

where  $2E_{0,1}^\circ - E_{0,2}^\circ = D_{C_2}$ , the dissociation energy of  $C_2$  into two normal carbon atoms. Table III. gives the  $\log_{10} K$  values for  $D_{C_2} = 125$  kcal.

TABLE III.—EQUILIBRIUM CONSTANT OF THE EQUILIBRIUM  $C_2 = 2C - D_{C_2}$ . CALCULATED FOR  $D_{C_2} = 125$  KCAL.

T° K.	2000	2500	3000	3500	4000	4500	5000
$\log_{10} K$	8.5	5.8	4.0	2.7	1.8	1.1	0.5

4. In the figure we have plotted the three sets of calculated values of  $\log_{10} P_1$  against  $1/T$  (curves a) as well as the curves representing the

<sup>23</sup> Gibson and W. Heitler, *Z. Physik*, 1928, 49, 465.

experimental observations. It is clear that the three calculated curves are widely separated, even if considerable errors were made in the calculations; this is still more the case for the curves (b) in which allowance is made for  $C_2$  in equilibrium with C.

The lowest values for the vapour pressure, *i.e.*, the highest values for the heat of evaporation were obtained by the measurements of vaporisation rates by Wertenstein and Jedrzejewski and Marshall and Norton.<sup>4</sup> Since this method always gives too low values, it can be understood that the experimental vapour pressure was found only between 1 per cent. (Wertenstein and Jedrzejewski) and 10 per cent. (Marshall and Norton) of the values calculated with  $L_C = 168.8$  kcal., whereas the disagreement with the other curves is more than 4 powers of 10.

FIG. 1.

On the other hand, we have to consider the fraction of  $C_2$  in the carbon vapour. The corresponding curves in the figure are marked with a "b." In the case of  $L_C = 168.8$  kcal. we obtain with the equilibrium constants of Table III. the figures given in Table IV.

TABLE IV.—PARTIAL PRESSURE OF  $C_2$  AND TOTAL VAPOUR PRESSURE OF CARBON CALCULATED FOR  $L_0 = 168.8$  KCAL. AND  $D_{O_2} = 125$  KCAL.

	T° K.	2000	2500	3000	3500	4000	4500	5000
$\log_{10} P_2$	(atm.)	-12.45	-7.75	-4.6	-2.4	-0.8	+0.35	+1.3
$\log_{10} P$	Total.	-10.38	-6.64	-4.07	-1.92	-0.65	+0.44	+1.37

As can be seen in the figure, this gives a sufficiently good agreement with Kohn and Guckel and Ryschkewitsch' measurements with the arc method.

We arrive thus at the curious result that direct experimental evidence favours the vapour pressure curve which we have to reject on spectroscopic grounds. As a matter of fact, Thiel and Ritter's measurements, although the authors do not claim a high degree of precision, seem to be more in favour of  $L_C = 123.6$  kcal. (see the figure), and it is always much easier to understand that equilibrium pressure has not been obtained, than the existence of a pressure which is higher than equilibrium. Furthermore, according to K. Warmuth,<sup>24</sup> Kohn and Guckel's temperature values were too high, *i.e.*, their vapour pressure values too low, and this would equally favour  $L_C = 123.6$  kcal.<sup>25</sup> However, even if we take these points into account, this curve lies very high, and it seems necessary to assume that the vapour pressure of monatomic carbon is practically equal to the total pressure, at least in the lower temperature range, say up to about 2500 or 3000° K. This is only possible for  $D_{C_2} \sim 4$  v.c.; curve (b) for  $L_C = 123.6$  and 107.2 kcal. has been calculated with this value. Even in this case the vapour pressure reaches a value of 1 mm. at about 2500° and of 1 atmosphere near 3100° K. This is an order of magnitude by several powers of 10 higher than any value hitherto accepted, and it seemed interesting to undertake vapour pressure measurements with a new direct method, especially since the present calculations show that it is sufficient to determine the order of magnitude in order to decide between the different curves and thus obtain an extremely precise value; we hope to publish soon the results of the new measurements which are now in preparation.

Since  $L_C = 123.6$  kcal. gives already unexpectedly high values for the vapour pressure, this is *a fortiori* the case for  $L_C = 107.2$  kcal.; in this case, even for so low a value of  $D_{C_2}$  as 4 v., carbon vapour would be composed practically of  $C_2$  at all temperatures (curve b). A pressure of 1 mm. would be reached at about 1900° K. and 1 atmosphere near 2500° K. This is about 1000 times higher than for  $L_C = 123.6$  kcal.

Therefore, also Schmid and Gerö's<sup>15</sup> value of  $D_{CO} = 6.9$  v. ( $L_C \sim 78$  kcal.) must be considered highly improbable. These authors assume that the evaporation gives carbon atoms in the  $^5S$  state: such an interpretation could be possible for dynamical experiments (rate of evaporation). We have to consider, however, that in equilibrium, for such a low value of  $L_C$ , practically all the carbon vapour is diatomic, therefore the energy change  $\Delta E$  of the evaporation is given by equation (1) that is  $\Delta E = L_C$  about 73 kcal. for  $D_{CO} = 6.9$  v. It seems very improbable that a vapour pressure of the order of that of silver, should never have been observed in the case of carbon, for example, in highly heated carbon tubes.

### Summary.

1. Three values of the heat of vaporisation of carbon  $L_0 = 168.8$ ; 123.6; and 107.2 kcal. are discussed. These values were obtained from three values of the dissociation energy of carbon monoxide which are in agreement with the predissociation limit at 11.06 v. The vapour pressure curves of carbon were calculated for these values. Intermediate values can be ruled out by spectroscopic arguments.

2. The direct measurements of the vapour pressure of carbon described in the literature lie mostly between the curves calculated for  $L_C = 168.8$

<sup>24</sup> *Wissenschaftli. Veröffentl. des Siemenskonzerns*, 1928, 7, 307; *Chemisches Zentralblatt*, 1928, 2, 1800.

<sup>25</sup> The temperature scale of Ryschkewitsch was practically the same as Kohn and Guckels, so that his results should also be corrected.

kcal. and 123.6 kcal.; only the values obtained from the rate of evaporation give lower vapour pressures than higher heats of vaporisation.  $L_0 = 168.8$  kcal. gives the best agreement but it cannot be accepted for spectroscopic reasons. The vapour pressure calculated from  $L_0 = 107.2$  kcal. or still smaller values, is by several powers of 10 higher than can be expected from available empirical data.

3. The most probable value of the heat of vaporisation of carbon is therefore  $L_0 = 123.6 \pm 0.5$  kcal. The corresponding value for the dissociation energy of carbon monoxide is  $D_{CO} = 9.10 \pm 0.005$  v. = 209.9 kcal. The dissociation energy of  $C_2$  is probably of the order of  $D_{C_2} \sim 4$  v.  $\sim 90$  kcal.

We wish to thank our friends, W. Lasareff, M. Letort, and B. Rosen for many valuable discussions, and R. B. Mooney for correcting the manuscript.

One of us (P. G.) wishes to express his gratitude to Professor Jules Duesberg, Recteur de l'Université de Liège for giving him the opportunity of working at that University. His thanks are also due to Professor V. Henri for his hospitality in his laboratory.

Bruxelles.*

## THE ACTION OF ULTRASONIC WAVES IN SUSPENSIONS.

BY F. J. BURGER AND K. SÖLLNER.

*Received 27th July, 1936.*

In a recent paper<sup>1</sup> the formation of stationary wave patterns (Kundt's dust figures in liquids) in emulsions and suspensions caused by ultrasonic waves has been discussed.

A number of other phenomena observed in colloidal or semi-colloidal systems exposed to ultrasonics were found to be connected with this general effect. They are:

(1) The orientation of anisometric (*i.e.*, rod or plate-shaped) particles in an ultrasonic field.

(2) The solidification of concentrated suspensions (rheopectic solidification by sound).

(3) The neutralisation of dilatancy by an ultrasonic field.

A characteristic feature of all systems which exhibit these phenomena is that the particles are big enough to be influenced individually by the sound waves, contrary to the behaviour of normal gels (*e.g.*, iron oxide or gelatin gels), where the disperse system behaves like a continuous homogeneous system of which the particles are so small that energy cannot be scattered by them to any appreciable extent.<sup>2</sup>

### I. Orientation by Ultrasonics.

When investigating the formation of stationary wave patterns in a field of ultrasonics<sup>1</sup> it was natural to expect that non-spherical particles might be orientated with their longer axis normal to the flux of energy.

<sup>1</sup> K. Söllner and C. Bondy, *Trans. Faraday Soc.*, 1936, **32**, 616.

<sup>2</sup> H. Freundlich and K. Söllner, *ibid.*, 966.

This was tested by applying a field of moderate energy to rather dilute suspensions prepared from rod- or plate-like particles and using suitable containers. Macroscopic pieces of glass or quartz wool and also small plates of mica and mosaic gold which were lying flat in a horizontal tube prior to irradiation, are orientating themselves by assuming a position normal towards the flux of energy (this being parallel with the axis of the tube) as soon as not too weak a field is applied, in this way forming stationary wave patterns.

It is advisable in this experiment and all following ones to secure an electric charge of the particles by adding a suitable electrolyte, generally  $\text{NH}_4 \cdot \text{OH}$ , otherwise coagulation may become a source of trouble. Furthermore it is here advisable to use partially degassed water.<sup>1</sup>

Suspensions of rather fine asbestos fibres possessing only a slight tendency to settle, show the same phenomena when irradiated in a long vertical test- or U-shaped-tube, the particles first being orientated and later on accumulated in the liquid.

An orientation is also indicated by the appearance of a silky gloss in the zones of accumulation of the sediments in horizontal tubes when irradiating similar suspensions containing particles too small to be seen individually. According to the nature and size of the particles the phenomenon may persist (in the sediment) for some time after the irradiation has been discontinued.

With very small energies an impressive demonstration of the orientation phenomenon can be given by using highly dilute suspensions (e.g., of mica, whose particles are too small to settle even in a considerable length of time). It was found most suitable to use long U-shaped tubes (height 20-40 cm., inner diameter 2-5 mm.) held in an upright position. The observations are made in transmitted light. Brilliantly glittering zones at more or less regular half-wave distances appear immediately the specimens are held in the oil. The vibration there is hardly perceptible, the energy being only 20 to 30 mA.

With such low energies no accumulation in any reasonably short period takes place. One notices further that accumulation as found at higher energies persists for some time after the irradiation has ceased, but that orientation of these small particles disappears at once.

The strongest glittering always appears to be at the antinodes. The glittering zones of orientation show a slight incessantly fluctuating motion, because of the somewhat irregular energy transmission, which tends to displace the meniscus. Simultaneously with this the zones of orientation are displaced. They do not disappear, as do the accumulations (formed at higher energies), when the meniscus is displaced.

Individual particles can be seen glittering at one spot for a considerable time, thus proving that the orientation is brought about directly by the sound waves and not indirectly by some kind of streaming or vortex motion in the liquid.

Orientation is in no way linked up with cavitation. This was also confirmed for accumulation.<sup>1</sup> Both effects are equally well produced *in vacuo* and when increased external pressure is applied. *In vacuo* the bubbling and boiling of the liquid must of course be avoided by lowering the energy, otherwise the phenomenon cannot be observed well.

No glittering on irradiation is found with systems containing spherical particles such as emulsions of nitrobenzene or benzene or suspensions of specially prepared glass spheres. After some time of irradiation at low energies, but more rapidly with higher energies, accumulation can be seen, but never any glittering. The difference is so striking that the occurrence of the glittering phenomenon cannot be misjudged.

Other circumstances being equal, bigger particles in suspension are more readily orientated than smaller ones. The same holds in respect of their accumulation.<sup>1</sup> Here quartz powders of definite particle size may be used, quartz powder being another substance easy to orientate by

ultrasonics. Three U-shaped tubes containing quartz powder suspensions with particles from  $4$  to  $10\mu$  diameter,  $1$  to  $4\mu$ , and smaller than  $1\mu$  respectively, were irradiated with medium energy: the  $4$  to  $10\mu$  suspensions showed at once distinct glittering; subsequently the  $1-4\mu$  suspensions followed showing a weaker effect, finally came the finest suspension, the effect here being still weaker and not increasing, even after many seconds. It became distinct only when the energy was increased.

Mica is the substance most suitable for demonstrating orientation. A suspension containing thin plates of a few  $\mu$  and less maximal diameter and only so few in number that a turbidity can just be perceived, shows an excellent effect when irradiated with moderate energy.

Other substances, gypsum, steatite, selenite, mosaic gold and quartz powder as mentioned above (diameters up to  $20\mu$ ) show distinct orientation at moderate energy. Similar behaviour is shown by clay with a particle size of several  $\mu$  and below, by kaolin ("Stockalite"), whose particles are mainly below  $1\mu$ ; and by colloidal graphite in water ("Aquadag," E. G. Acheson Ltd.). In these cases, especially in the last, the orientation is seen at higher energies not only in transmitted but also in reflected light.

Orientation has so far been found in two typical colloidal solutions, viz.:  $V_2O_5$  and  $Fe_3O_4$ . Rather concentrated (about 1.2 per cent.)  $V_2O_5$ -sols, of high "viscosity," containing particles up to  $10$  and  $15\mu$  length were used. (Owing to their extreme thinness these particles can only be seen in the ultramicroscope.) Filled into a U-shaped tube and irradiated with not too low an energy these sols slowly take on a silk-like appearance, the streaks—in conformity with the orientation of the particles—adjusting themselves perpendicular to the axis of the tube. After a minute or so the phenomenon is very pronounced, persisting for many hours or even days, due to the gel-like state of this sol.<sup>3</sup> On close observation one sees that the particles are orientated directly and not by some kind of streaming of the liquid; for bigger particles or flakes contained in the sol remain motionless during irradiation.

When diluted four times the same sol shows the orientation—which can only be seen in reflected light—much more quickly, due to its greater fluidity. Regular half-wave structure appears. This is due to the fact that orientation is better developed in the antinodes than in the nodes (see above). In one (diluted) sol only, containing very big ( $10-15\mu$ ) particles, was a very slight accumulation occasionally observed. On diluting the original  $V_2O_5$ -sol fifty or one hundred times, nothing can be seen in reflected light; transmitted polarised light however reveals a distinct orientation.

Similar results were obtained with a very dilute  $Fe_3O_4$ -sol, many years old, whose particles were ultramicroscopic in all three dimensions.

Though the whole matter still needs fuller investigation, one may now state that, with suitable substances, orientation can be obtained much more readily and with less energy than accumulation; also particles which are too small for accumulation may still become orientated. This is easily understood, because in order to obtain any appreciable accumulation, particles must be moved about several tenths of a millimeter, whereas orientation is effected by simply turning the particles into the favourable position, the maximum movement necessary being only of an order comparable with the length of the particles.<sup>4</sup>

Such orientation could perhaps be utilised for manipulating the interior

<sup>3</sup> Orientation is particularly strong in sols which tend to form tactoids. (For literature on tactoids, cf., e.g., H. Freundlich, *Kapillarchemie*, Vol. II., 1932, pp. 54 ff.) Thus it seems worth while to investigate, whether there exists an influence of ultrasonics upon the formation of tactoids.

<sup>4</sup> The formation of non-spherical aggregates during the coagulation of smoke as described by O. Brandt and E. Hiedemann (*Trans. Faraday Soc.*, 1936, **32**, 1101) may be partially caused by a similar orientation effect in gaseous systems.

of closed systems (e.g., living cells) without using any mechanical devices, which might be obnoxious.

## II. Rheopectic Solidification Caused by Ultrasonics.

The time of solidification of certain types of thixotropic systems is shortened by submitting them to a more or less regular movement, such as tapping the test-tube containing the sol or slowly rolling it to and fro between the palms of the hands. This phenomenon was called rheoexy.<sup>5</sup> Rheopectic solidification seems to have a relationship to coagulation produced by stirring.

After it had been found that irradiation with ultrasonic waves may also cause rheopectic solidification<sup>6</sup> it seemed worth while to investigate the latter phenomenon more closely, particularly in order to see whether it is connected with the local accumulations caused by stationary waves in suspensions<sup>1</sup> and with the orientation of non-spherical particles described above.

At first we studied suspensions of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ . Their particles ranged at first from about  $1$  to  $10\mu$ ; later owing to their solubility they grew to from  $10$ - $30\mu$ ; this did not alter their behaviour appreciably. Specimens of gypsum suspensions in distilled  $\text{H}_2\text{O}$  were prepared and sampled in test-tubes of  $1.2$  cm. diameter which were later sealed, the concentrations of  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  ranging from 20 per cent. up to 30 per cent.; sedimentation of the suspensions becomes conspicuous after standing for about an hour. Rheopectic solidification could be produced by subjecting the samples to a weak ultrasonic field for a few seconds. Several minutes or hours are required for spontaneous solidification. The lowest concentration for which the effect can be observed is 23 per cent.; below this the gypsum particles are only accumulated forming stationary wave patterns.

On close inspection it was seen that the samples containing the higher concentrated suspensions also show accumulation.<sup>7</sup>

The behaviour of a sample of kaolin ("Stockalite" above-mentioned) was similar. Its particles are anisometric, because a dilute suspension shows the orientation phenomenon; aqueous suspensions containing as much as 60 per cent. solid matter are quite liquid. These suspensions are very poor as regards plasticity and thixotropy. By addition of  $\text{NaCl}$  solution the charge of the particles is however lowered and Stockalite, thus partly coagulated, forms thixotropic and rheopectic suspensions. For example, 5 g. Stockalite + 8 c.c. 2N  $\text{NaCl}$  solution remained liquid for at least 17 minutes in a test-tube; on prolonged standing sedimentation can be observed. Upon tapping this suspension solidifies after 30 seconds; in an ultrasonic field of moderate energy (70 mA) only 15 seconds are required. When irradiating for a longer time zones of accumulation are gradually forming in the paste, preferably in narrow tubes.

<sup>5</sup> H. Freundlich and F. Juliusburger, *Trans. Faraday Soc.*, 1935, **31**, 920.

<sup>6</sup> F. Juliusburger and A. Pirquet, *Trans. Faraday Soc.*, 1936, **32**, 445.

<sup>7</sup> We also tested, whether or not the rheopectic solidification by ultrasonics is due to cavitation (cf. C. Bondy and K. Söllner, *Trans. Faraday Soc.*, 1935, **31**, 835 and <sup>8</sup>). Both under gas pressure and *in vacuo* (bubbling and boiling must of course be carefully avoided) solidification occurs as usual—therefore cavitation need not be considered here. On the other hand rheopectic pastes and gels can of course be disrupted and liquefied when ultrasonics of higher energy are applied. In this respect they do not differ at all from normal thixotropic gels.<sup>8</sup> The only difference is that, at moderate energies where the effects of cavitation are negligible, systems with very small particles (e.g., thixotropic iron oxide) are not influenced appreciably, whereas systems with larger particles, big enough to be moved individually by the sound waves, may be solidified.

While with the gypsum or Stockalite suspensions the rôle of orientation of the particles cannot be excluded, in addition to the obviously effective accumulation, the latter is certainly solely responsible in the next system, showing rheopexy when irradiated.

Suspensions or sludges of Solnhofen slate<sup>a</sup> are rheopeptic, when in a suitable concentration. They also are solidified when irradiated with ultrasound. A temperature of about 35° C. proved favourable. Medium energy (75 mA) was sufficient to solidify the sample in about 3 seconds while the spontaneous solidification occurs in about 30 seconds. The particles of Solnhofen slate do not deviate much from a cubical shape; they, also, do not show an orientation effect. Therefore, in this case at least, rheopexy is possible without orientation, the accumulation of the discharged particles being most likely the only cause of their becoming a paste.

Plastic clay, as used for moulding purposes, shows rheopexy when in suitable concentrations, upon tapping or rolling the test-tube containing the sample to and fro. Its particles are anisometric, for dilute suspensions show the orientation phenomenon. The particles are several  $\mu$  in diameter and less, and show a weak (but distinct) tendency to form zones of accumulation when irradiated in dilute suspension.

It has however, so far, been impossible to detect a shortening of the time of solidification under various conditions of concentration and electrolyte present. These suspensions show hardly any tendency to settle down; however, in the more dilute ones, some supernatant liquid can be seen after very long standing.

The tendency to form stiff gels—as distinct from the rather soft pastes mentioned above—is obviously also the reason why rheopeptic solidification with ultrasonics cannot be observed. The individual particles are bound so firmly to one another that the whole system behaves as a coherent, more or less homogeneous, gel.<sup>a</sup> For this reason zones of accumulation have never been observed in concentrated systems of this kind, which, of course, are formed here too by big foreign particles.<sup>a</sup>

We can now also understand why rheopeptic solidification due to ultrasonics has so far not been observed in  $V_2O_5$ -sols (containing suitable electrolytes). These sols scarcely form any zones of accumulation when irradiated. Moreover, the particles, while readily orientated in dilute solutions, are much more slowly orientated in concentrated ones. The interaction between the particles is obviously so strong, that accumulation and even orientation by sound waves is rendered impossible.

These experiments lead to the conclusion that, generally speaking, rheopexy is not necessarily linked up with orientation and that a solidifying influence of ultrasonics is to be expected in those rheopeptic systems, which are more paste- than gel-like and whose particles are big enough to be influenced—by being either orientated or moved—individually by the sound waves.

### III. Neutralisation of Dilatancy by Ultrasonics.

If the supernatant liquid is poured off the sediments of various suspensions such as quartz powder or sea-sand, the sediments are somewhat moist and soft, when only a slight pressure is applied. As soon as however a stronger, one-sided, pressure is acting, a sediment of this kind becomes dry and hard and offers considerable resistance to a penetrating instrument; as soon as the pressure ceases the whole mass

<sup>a</sup> On the thixotropy and plasticity of Solnhofen slate, *cf.*, Freundlich and F. Juliusburger, *Trans. Faraday Soc.*, 1934, **30**, 333.

<sup>a</sup> H. Freundlich and K. Söliner, *ibid.*, 1936, **32**, 966.

usually becomes moist again. This phenomenon called "dilatancy" was explained by Osborne-Reynolds,<sup>10</sup> in the following way: In moist sand the particles tend to assume a very close-packing. If an external force displaces the particles the packing becomes looser and consequently water is sucked in, thus leaving the sediment apparently dry and hard.

When a system normally exhibiting dilatancy is exposed to ultrasonics dilatancy disappears so long as a sufficiently strong field is in action: *e.g.*, a beaker was filled with some quartz sand ("silver sand") and water was added so that the system showed dilatancy. It was not possible to drive a test tube through the sand to the bottom of the vessel. This however was quite easy as soon as a strong ultrasonic field was applied, exposing the beaker to the oil fountain.

A very similar experiment can be carried out using fine quartz powder instead of the sand. In this case more energy is necessary, because owing to the increased scattering surface formed by the much smaller particles the resistance to the sound waves is increased.

In a further experiment, a sediment of quartz sand was freed carefully from all supernatant and adhering water after standing for quite a long time. Its appearance was very dry. When irradiated for several seconds it gave off about 0.5 to 1.0 c.c. water per 100 c.c. sediment. After this water was poured away the sand offered a very great resistance to a penetrating test-tube from the very start. This experiment shows that the sand under the influence of the ultrasonics assumes a packing closer than after being left undisturbed for quite a long time or after being tapped frequently in order to promote settling. Applying a rather high energy (135 mA) it is possible to destroy dilatancy in a beaker containing 2 kg. silver sand mixed with the necessary amount of water.

Here we see how apparently dilatant and, therefore, non-plastic systems, can be rendered somewhat plastic by applying ultrasonics. It can readily be shown that cavitation is not connected with the influence of ultrasonics on dilatancy.

### Summary.

(1) With ultrasonics rod- or plate-like particles (mica, mosaic gold, gypsum, selenite, steatite, quartz, kaolin, etc.) can be orientated with their longest axis normal to the flux of energy. To produce this effect the energy may be below the limit necessary for accumulation. These results are obtained as a rule with particles of microscopic size, but orientation was also found in truly colloidal solutions of  $V_2O_5$  and  $Fe_2O_3$ .

(2) Concentrated rheopectic suspensions of gypsum, kaolin and Solnhofen slate are solidified by ultrasonics of low and medium energy. The solidification is correlated to the accumulation of the particles by ultrasonics. If the energy applied is sufficiently high, these concentrated pastes also can be liquefied, as a consequence of cavitation.

(3) Mixtures of sea-sand or quartz-powder with water which are normally dilatant lose this property, when exposed to ultrasonic waves.

Our sincerest thanks are due to Professor H. Freundlich for his continuous interest and very helpful criticism during our work. We are also greatly indebted to Professor F. G. Donnan, F.R.S., for his generous hospitality.

# THE ETCHING OF COPPER BY OXYGEN.

By C. F. ELAM (Mrs. G. H. TIPPER).

Received 10th August, 1936.

## Part I.

Metals heated *in vacuo* frequently etch, *i.e.*, the structure is revealed by partial volatilisation or other surface changes. A very beautiful example is shown in a photograph of pure silver in Rosenhain's *Introduction to Physical Metallurgy*. This photograph not only shows crystal boundaries, but also a series of lamellæ in certain crystals which change direction at crystal and twin boundaries and very much resemble slip-bands in appearance. Such a structure can also be produced on copper when a specimen is heated *in vacuo* at 900-950° C. Figs. 1-6, Plate I, are representative photo micrographs. It will be seen that some crystals are quite free from lamellæ. In others, the lamellæ are straight, while in others again they are curved to a considerable extent. The spacing also varies from crystal to crystal. The iridescent nature of the reflection of light by this etched surface is very striking and, as in the case of pearlite in steel, the cause is similar. In view of the recent interest in the internal structure of crystals, it was decided to investigate the nature of these lamellæ further in order to see what relation they bore to the crystal, if there were any regularity in spacing and further, if they changed in character with different copper and with different treatments.

The first step was to prepare copper crystals large enough for X-ray measurements on which two or more faces could be ground in order to determine the planes (if any) made by the lamellæ themselves. Large copper crystals can easily be made by Bridgman's method using graphite tubes in which to melt the copper, but these crystals did not etch on heating *in vacuo*. Working and annealing the copper failed to produce any effect and the conclusion was come to that the copper was at fault. Other samples of copper available heated in the same tube, at the same time etched, so that the question naturally arose as to why the copper melted in graphite tubes did not. At this stage I applied to the British

[See page 1613]

Non-Ferrous Metals Research Association for samples of copper, one of which was to be the purest available and oxygen-free, and they very kindly supplied me with three different coppers and their spectrographic analyses. AJK and ARQ were cast ingots. AJK was a sample of high conductivity oxygen-free copper; ARQ was a small wire bar of tough-pitch fire refined copper. CJR was cathode copper straight from the cathode.

These coppers were all very pure and only ARQ contained any cuprous oxide. Pieces were cut from them and samples from AJK and ARQ were rolled and then annealed *in vacuo*. Heating was carried out in an alundum boat in a fused silica tube having a ground glass joint to make the necessary connections with the pump. The pump was a Hyvac, which if kept running continuously, gave a vacuum of less than 0.5 mm. pressure. Gases were given out by the metal and tube on heating and if the pump were shut off the pressure sometimes rose 2-3 mm. Of three coppers referred to above, the only specimens that etched were those cut from ARQ.

At this stage the presence of cuprous oxide was suspected of being responsible, and experiments were carried out accordingly. It was noticed that all the coppers that etched contained visible amounts of cuprous oxide. Although the rods from which large copper crystals were made contained a certain amount of oxide, the crystals grown from them, whether melting was carried out in air or nitrogen, contained only traces. What remained was confined to a few minute isolated inclusions at the crystal boundaries. If then, this effect is due to the presence of oxide, treatment removing the oxide should prevent its occurrence. Samples of a number of coppers including ARQ and AJK were heated in a stream of hydrogen at 900° C. for five hours. Those containing cuprous oxide cracked badly under this treatment, but AJK and a piece of a large crystal remained sound. On subsequent heating *in vacuo*, none of them etched. The next step was to add oxide to a copper such as AJK. Certain difficulties were here met with. If melting was carried out in graphite tubes and even a large excess of cuprous oxide rolled up in copper foil added, only traces of oxide remained in the copper. If the same procedure was carried out in alundum crucibles the oxide attacked the crucible and everything went through the pot. Finally, the copper was melted and the oxide added and the metal cooled quickly. This method was successful in introducing the oxide but the crystals in the small ingot—about 60 gms.—were consequently small. Specimens cut from such an ingot etched with ease, and thus provided striking confirmation of the necessity for the presence of oxide. It was also noticed that with repeated heatings, the tendency to etch decreased and finally disappeared with corresponding loss of cuprous oxide. This suggested diffusion of oxygen through the copper crystals and in order to test this further the following experiments were made. A plug of the copper made from AJK containing cuprous oxide was put into a piece of AJK as received, and the two heated in contact for 5 hours at 900° C. The polished surface showed the cuprous oxide in the plug had gone, and the surrounding AJK was pitted but not etched. A section cut and polished showed a core of the plug containing oxide, a narrow rim in which the oxide had disappeared, and a halo effect in AJK was obtained on etching with ammonia which spread outwards on subsequent heating. Similarly, a piece of a bar produced by melting in a graphite tube and showing three large crystals in section, was put as a plug into a sample of ARQ, a section cut and polished and heated at 900° C. *in vacuo* for five hours. The crystals in the plug now etched as well as the surrounding copper. Finally a section of this was cut and polished and heated a second time and this also showed a faint etch.

These experiments, although only qualitative in character, seem sufficient to warrant the assertion that the presence of cuprous oxide is the prime cause of the etching observed. The alundum boat became pink

and also the inside of the silica tube, particularly round the region just inside the furnace. After prolonged heating the boat became white again. Slade and Farrow<sup>1</sup> state that cuprous oxide can be volatilised and this was confirmed by heating some freshly precipitated and dried  $\text{Cu}_2\text{O}$  in the silica tube at  $900^\circ\text{C}$ ., when the oxide left the boat and collected round the cooler part of the tube. This is contrary to the findings of Rhines and Mathewson<sup>2</sup> who, although they found loss of  $\text{Cu}_2\text{O}$  on heating *in vacuo*, say that the oxide was reduced and decomposed. Tiede and Birnbrauer<sup>3</sup> noticed a liberation at  $960^\circ\text{C}$ . of a red substance, which they assumed to be copper, on heating copper *in vacuo*. Copper did not come off with any freedom till  $1360^\circ\text{C}$ . and it is possible that their first evolution was  $\text{Cu}_2\text{O}$ .

Further experiments were then carried out to see if the same effect could be produced by oxidising the surface and then volatilising off the layer of  $\text{Cu}_2\text{O}$ . Oxidation was affected by opening a tap when the metal was hot and letting in a little air. If this was done with the tube withdrawn (the metal itself remained hot in a vacuum long after the tube was out of the furnace) the bright surface of the copper was seen to dull. If the copper was still about  $750^\circ\text{C}$ . and a very small amount of air let in, the surface tarnished over and then brightened again immediately. As more air entered the coating of oxide persisted and if the specimens were allowed to cool it appeared black. If the tube was then evacuated and heated at  $900\text{--}950^\circ\text{C}$ ., the coating was distinctly red, i.e.,  $\text{Cu}_2\text{O}$ . The outline of the original crystals was clearly indicated in the oxide. After further heating *in vacuo*, varying from 1 to 20 hours according to the thickness of the oxide layer, the whole of the layer disappeared leaving the copper bright and beautifully etched.

As a further check on the results described above, Dr. W. E. Alkins was instrumental in obtaining some special silver-free copper and a further oxygen-free-copper carefully prepared to avoid contamination with oxygen. The silver-free copper contained about 0.016 per cent. oxygen and etched very slightly on heating. By allowing a slight artificial oxidation of the surface it etched as well as any other copper. The specially prepared oxygen-free copper on the other hand did not etch.

It is now possible to speculate a little about the possible causes of this etching effect. It has been shown conclusively that the presence of cuprous oxide in the copper or a layer of oxide on the surface is necessary.

If two samples, one of which etches and the other does not, are heated together in the tube, the one that etches does not effect the other, but if the two are in intimate contact, then the copper which does not etch tends to do so. It seems justifiable to conclude that oxygen diffuses through the copper and on arrival at the surface forms a layer of cuprous oxide which at the correct temperature and pressure volatilises. Recent estimations<sup>4</sup> of the solubility of oxygen in copper are as follows:—

600° C.	oxygen per cent.	0.0071
800° C.	" "	0.0094
950° C.	" "	0.0100

Although low, it is sufficient for the purpose, the supply of oxygen inside the specimen being provided by the cuprous oxide, which gradually disappears. The fact that the same effect can be reproduced artificially by oxidising the surface and then volatilising off the oxide suggests that this is a rough outline of what actually happens. The details of the process and the relative importance of temperature and pressure and oxide concentration are still obscure.

<sup>2</sup> F. N. Rhines, C. H. Mathewson, *Amer. Inst. Min. Met. Eng. Trans. Inst. Metals Div.*, 1934, 337.

<sup>3</sup> E. Tiede, E. Birnbrauer, *Z. anorg. Chem.*, 1914, 87, 129.

<sup>4</sup> F. N. Rhines, C. H. Mathewson, *Amer. Inst. Min. Met. Eng. Trans.*, 1934, p. 337.

In order to obtain some quantitative measurements of this phenomenon, a piece of oxygen-free copper AJK,  $7.58 \times 7.05 \times 16.31$  mm., was heated *in vacuo* at  $950^\circ$  C. twice and the weights compared. Constant weight was obtained. The specimen was then heated and oxidised, the air pumped off and further heated until the copper was bright again, cooled and weighed. The tube had a red coating inside in the cooler region. The figures are given in Table II. This process was repeated. In the

TABLE II.

	Gms.
After 1st heat at $950^\circ$ C. for 3 hours . . .	7.420
After 2nd heat at $950^\circ$ C. for 4 hours . . .	7.420
Heated to $950^\circ$ C., air let in . . .	—
Heated <i>in vacuo</i> at $950^\circ$ C. till oxide on surface had gone. Oxide still on under side. Tube had red deposit . . .	7.420
Heated 10 hours <i>in vacuo</i> at $950^\circ$ C. . .	7.419
Heated to $900^\circ$ C.; air let in; heated $\frac{1}{2}$ hour; then black. Heated 1 hour <i>in vacuo</i> ; then red . . .	7.421 (Increase in weight 0.002)
Heated $3\frac{1}{2}$ hours <i>in vacuo</i> at $900^\circ$ C. Red gone on specimen; tube coated red . . .	7.420
Heated <i>in vacuo</i> $2\frac{1}{2}$ hours at $920^\circ$ C. . .	7.419
Heated 14 hours at $950^\circ$ C. <i>in vacuo</i> . . .	7.417 (Loss of weight 0.002)
Heated in hydrogen at $900^\circ$ C. for 1 hour. Total heating and cooling period $5\frac{1}{2}$ hours . . .	7.417 (No further loss).
Colorimetric estimation of copper in $\text{Cu}_2\text{O}$ on tube . . .	0.0022

second experiment the specimen was weighed with the oxide coating. The increase in weight does not necessarily represent the total amount of oxidation as some of the oxide was probably lost immediately the air was pumped off. An approximate calculation of the thickness of the oxide layer gave it as 0.5 mm. assuming that the oxide was uniform over the whole area of surface. The specimen was then heated until it was bright. A slight red stain remained on the alundum boat and the inside of the silica tube was red. There was a distinct loss of weight of the copper and cuprous oxide was found on the inside of the tube. The quantitative relations between loss of weight and amount of oxide on the tube are not likely to be accurate but this experiment provides conclusive proof that cuprous oxide is volatile. It may be suggested that the oxide is decomposed and reformed on the tube, but this is unlikely as the unoxidised copper was shown to be not volatile at  $950^\circ$  C.

The fact that there is no further loss of weight on heating in hydrogen shows that the oxide had all come off in the vacuum heating. The discrepancy between loss of weight and amount of copper found on the tube may be accounted for by the fact that some oxide adhering to the tube from previous heatings was included in the analysis. The tube becomes permanently red after repeated use due to attack of the silica by the oxide.

It is possible that this method of removing oxide from copper might be made use of in the detection and estimation of cuprous oxide in copper. The present experiments are not sufficiently complete to say how far the method might be made applicable to all coppers because loss of weight alone might be due to the presence of volatile substances such as sulphur.

## Part II.

In order to make a full investigation of the striations it was necessary to work with copper crystals sufficiently large to enable more than one

face to be examined. At first, no striations could be obtained on large crystals made from the melt, so it was decided to grow crystals by the straining method in rod and strip. The objection to crystals produced in this manner is that they are always twinned and determination of the crystal axes by means of X-rays becomes more difficult. On the other hand when two or more sets of twins are present, determination of the crystal axes can be made by measurement of the traces of the twin bands on two sections at right angles. It is well known that the twin planes of copper are octahedral planes, hence the position of any two such planes is all that is required.

For this purpose some  $\frac{1}{8}$ -inch diameter copper rods were obtained through the kindness of Dr. Alkins from Thomas Bolton & Sons. These were cut from a high conductivity wire bar and contained a considerable amount of visible oxide. Crystals 2 cms. long and occupying the whole cross section were obtained, but, as has been said, they showed twinning. These crystals were compared with those made from the melt and treated as described in Part I. and no difference was observed.

In order to find the relation of the striations to the crystal structure, measurements were made of the angle between them and one edge of the face under observation or a scratch on the surface. Determination of the crystal axes by means of X-rays or measurement of the traces of twin planes were also made and the two series of measurements compared. Striations were obtained on two or sometimes three faces ground on the same crystal, but this was not always possible if the crystals were small. This entailed polishing several faces of a specimen before heating so as to be quite sure that all faces were subjected to the same conditions at the same time.

It was usual to find only one set of lines on each face, but there were cases of two appearing. Sometimes the lines were curved and wavy and could not be measured accurately. It is easy to see how such curved lines can arise. Suppose the lines represent traces of planes in the crystal which are nearly parallel with the face of the specimen. Then, any irregularities of the surface would cut the crystal planes in an irregular manner.

The spacing of the lines varied from crystal to crystal as Figs. 1-6, Plate I., show. This again may depend on the angle which the plane makes with the face.

If the planes are of the same indices the distance between them is the same,  $d$ , and the distance between successive traces on the surface is  $d \csc \alpha$ , if  $\alpha$  is the angle between the plane and the surface.

Actual measurements of the number of the striations to the millimetre, for example, were abandoned owing to the irregularity of spacing, but it is quite clear that, taking the crystal as a whole, spacing is characteristic of each grain. Absence of striations may indicate that the plane coincides with the face of the specimen or is at right angles to it.

Repeated treatments of one face always resulted in the same set of striations appearing and parallel faces cut on one crystal gave similar measurements. Separate specimens cut from the same crystal also showed the same striations on comparable faces. It seemed, therefore, that they must be related to the copper crystal.

In order to depict the combined results, stereographic diagrams were made of the crystal and positions of the striations marked. If these are related to the copper crystal and represent traces of a single plane, the pole of the plane would be expected to coincide with that of a possible crystal plane in the copper. Assuming that this was the case the pole of a plane which would cut the faces of the specimen in the directions observed, was marked on the stereographic diagram of each crystal and in only one instance did it agree with a likely crystal plane. If, however, the striations represent traces of different planes on different faces, no such relationship will exist. Moreover, if three faces were cut at right angles to each other and treated, confirmation was obtained of the fact that these were purely

surface markings, in that traces observed on the third face did not agree with any possible plane through both the other traces. This is not surprising, since we know that the marks are caused by oxidation of the surface and each face will probably act independently.

Reference to Fig. 7 will make these points clear, and a summary of results with other crystals is given in Table III.

It has been assumed that only important crystal planes need be considered. The agreement between striations and traces of possible planes was good, and it does not seem to be necessary to give actual measurements in each case. Where the striations marked on the diagrams coincided with the pole of an important crystal plane, *i.e.*, (110) for example, more

FIG. 7.— $G_3$ .

$S_1 = (\bar{1}10)$ ,  $S_2 = (100)$ ,  $S_3 = (001)$ .

than one interpretation was possible, as several possible planes pass through this point. The (111) planes must be included but only one case was met with in which a (111) plane was the *only* possible plane.

From Table I. it appears that most of the striations are possible traces of (100) or (110) planes, and that it is rarely the same plane on two faces. The question naturally arises what relationship do these planes bear to the surface? Assuming that the striations have been correctly attributed to the crystal planes, a very wide variation is met with, and there is no obvious connection between angle of plane to the surface and formation of striations. In order to be quite sure on this point a comparison was made between the striations on the surface of the main crystal and its

twin bands. Knowing the form of twinning in copper, it is possible to calculate the position of the planes in each twin band. This was done for two faces of one crystal, and the results are given in Table IV. In this

case there can be no difference in composition which could affect the result and the angles between the planes and the surface are very different. There appeared to be no reason why bands corresponding to the twin on the  $(11\bar{1})$  plane showed no markings on Face II. This twin did not appear on Face I.

Special reference is necessary to three crystals in one specimen A, B and C, a photograph of which is shown in Figs. 5 and 6, Plate I. The striations on A and B were repeated in the same position every time the specimen was heated, but C had only a few faint markings. Comparing the orientation of the three crystals relative to the surface, it was found that in C, a  $\{100\}$  plane was perpendicular to the surface. If we assume that the striations are due to preferential attack by oxygen along certain planes—just as occurs by attack in solutions—the ends of all these planes being inclined at an angle to the surface, appear dark with vertical illumination. It is justifiable to assume that the “ends” are also crystal planes, also of type  $\{100\}$  or  $\{110\}$  planes. In crystal C, any attack along the  $(001)$  plane, would be perpendicular to the surface and no “step” would appear. It is probable, however, that the crystal being symmetrical to the surface, the attack may have been along a number of possible directions with the result that no one direction predominated and the surface remained smooth.

It is interesting to note that etching reagents attack copper crystals along directions corresponding to  $\{100\}$  and  $\{110\}$  planes.<sup>5</sup>

### Part III.

In order to try to account for the formation of the striations along certain planes in preference to others, an investigation was made of the structure of the oxide layer in its relation to the copper crystal. The specimen was polished and heated to the required temperature *in vacuo* and a few cubic centimetres of air let in. One experiment was made of letting in air before heating was begun. In some cases heating was continued in presence of air; in others the air was immediately pumped off and heating continued. It was generally found necessary to do this in order to insure that all the oxide was in the form of  $\text{Cu}_2\text{O}$ .

The structure of cuprous oxide<sup>6</sup> has been determined by means of X-rays and is face-centred cubic, the side of the elementary cube being  $4.25\text{\AA}$ . Each oxygen atom has four copper atoms arranged round it tetrahedrally.

It is difficult to estimate the thickness of the oxide layer but it was probably of the order of  $0.1$  to  $0.5$  mm.\* X-ray photographs always showed reflections from the copper crystals underneath in addition to those of the oxide. All the reflections from the oxide agreed with the theoretical structure of cuprous oxide with the dimensions given above. Instead of the well-defined spots obtained from single crystals, the reflections were often more in the nature of parts of rings, but showed marked concentration of intensity at certain points. This type of photograph is characteristic of those obtained from a number of small crystals showing preferred orientation along certain directions, *i.e.*, a “Fibre-structure.” A typical photograph is shown in Fig. 8, Plate II. This illustrates the difference between the reflections from the copper crystal and those from the oxide. It also shows quite clearly that the arrangement of the oxide is related to the copper. Copper has a face-centred cubic structure in which  $a = 3.61\text{\AA}$ . If the spacings for copper and the oxide are compared it will be found that in certain cases, *e.g.*,  $\{311\}$  planes in oxide and  $\{220\}$  plane of copper, they are very close but in others there is no agreement. Consequently it is unlikely that parallel growth in the true sense will take

<sup>5</sup> G. Tammann, *J. Inst. Metals*, 1930, 44, 29.

\* See p. 1607.

place. Fig. 8, Plate II., represents the typical structure of a thin film of oxide. In this case the crystal, (G 3), was heated in air from cold. The oxide crystals are arranged very nearly as the original copper. In order to compare this relationship, stereographic diagrams were made showing the positions of the oxide planes super-imposed on those of the copper crystal. In the case of the oxide, positions of maximum intensity are marked and the indices of the form only are given in brackets thus { }. Owing to the necessity of considering each face separately, it was not always possible to obtain sufficient reflections from the oxide to determine the orientation completely, as reflections from planes of higher indices were very faint and tended to form complete rings. In order to distinguish between those

FIG. 12.—G<sub>3</sub> coated Cu<sub>2</sub>O.

planes whose positions are obtained from the photograph and those calculated, the latter are underlined.

With thicker oxide films new spots appeared, Fig. 9, Plate II. is the photograph obtained from the same face of crystal G<sub>3</sub> as Fig. 8, Plate II. In this photograph we have reflections from the copper crystal; reflections corresponding to those obtained from the thin film; and a new series associated with a thicker film. A stereographic diagram of this crystal, Fig. 12 shows how the reflecting planes are related.

Reference to Plate II., Figs. 8-11 and Fig. 12 shows that reflections from {111} and {200} planes of the oxide very nearly coincide with the {111} plane of the copper crystal. This implies a double fibre structure for the oxide. In addition, there are certain reflections which indicate that some of the

oxide is still differently orientated. Reference to a stereographic projection of a cubic crystal shows that the pole of the (001) plane (for example) lies in the (110) plane and is  $54^{\circ} 44'$  from the (1 $\bar{1}$ 1) and (11 $\bar{1}$ ) planes respectively. In order to replace the (001) plane by the (1 $\bar{1}$ 1) plane it is necessary to rotate the (110) plane  $54^{\circ} 44'$  about its normal. At the same time the (001) plane replaces the (11 $\bar{1}$ ) plane. By this process we arrive at the structure found in the cuprous oxide and if this interpretation is correct a [110] direction should be common to both copper and oxide. In the case of crystal G, Fig. 12, this direction is the normal to the (110) plane in the diagram. Most of the oxide is thus arranged in two ways: (1) the orientation is nearly the same as the copper crystal; (2) a rotation of  $54^{\circ} 44'$  has taken place about a [110] direction. This structure is again typical of a fibre structure. Most of the reflections can be referred to one or other of the orientations given above, but a concentration of parts of {111} rings perpendicular to and at  $55^{\circ}$ - $60^{\circ}$  to the face indicates that some of the crystals are rotated through other angles about the [110] direction.

The oxide layers on crystals A, B and C and G<sub>1</sub>, <sub>2</sub> and <sub>3</sub> were fully investigated and all showed the same kind of structure. The degree of preferred orientation seemed to depend on the condition of the surface of the copper. The first coating of oxide showed less preferred orientation than a second deposited after the first layer had been volatilised off, even if the metal had been heated for some time at  $900^{\circ}$  C. before oxidising. The characteristic appearance may be compared in Fig. 14 and Figs. 8-11, Plate II.

Bircumshaw and Preston have also found by the electron diffraction method a preferred orientation of Cu<sub>2</sub>O on poly-crystalline copper, a {111} plane being parallel to the polished surface.<sup>7</sup>

The oxide crystals were so small that no individual spots were visible but after prolonged heating at  $950^{\circ}$  C. growth occurred as Fig. 14, Plate II. shows. It was also found that after heating at this temperature faint rings appeared on the X-ray film corresponding to pure copper indicating that some of the oxide had decomposed leaving small copper crystals on the surface. In most cases, repeated oxidation gave an oxide layer orientated in the same way, but in crystal C, different results were obtained.

The results show that the first layer follows the orientation of the copper closely, but that subsequent layers differ progressively. It is suggested that the outermost layers give rise to those reflections which do not fit either of the two principal orientations and approximate to a random arrangement.

### Discussion of Results.

The experiments just described are sufficient to warrant the assumption that the beautiful etching effect in copper and probably silver\* is due to an oxidation of the surface and subsequent volatilisation of the oxide in a high vacuum. Attack by solvents along certain planes in preference to others is a common occurrence and the regularity in the striations suggests a periodicity in the structure of the crystal. But the photographs show that the distance between successive striations is by no means constant although the average width of the bands is characteristic of each crystal. It was also noticed that there was very little difference between all the coppers examined and these had a variety of treatments. The most important cause of variation was the preparation of the surface and this is a difficulty that is not easily avoided. Even prolonged heating at  $950^{\circ}$  C. did not remove the effects of polishing. It is suggested that all mechanical methods of preparing a surface are

\* A few preliminary experiments have failed to obtain the etch effect in silver which was very pure and had been vacuum annealed.

<sup>7</sup> G. D. Preston, L. L. Bircumshaw, *Phil. Mag.*, 7, 1935, 20, 706.

likely to vitiate the results of the study of surface phenomena. The marked difference observed in the character of the X-ray reflections, whether the spots are well-defined; the presence of Debye rings, etc., is attributed to the perfection or otherwise of the surface.

It is well known that one substance will crystallise on another so that the orientation of both is the same if the two are isomorphous. In the present instance both substances are cubic although the lattice structure and dimensions are not identical. A certain degree of resemblance in orientation is to be expected but complete agreement is unlikely, and this is actually what is found. It is hoped that a full explanation of the formation of the oxide layer and the reason for the choice of orientation will be obtained and that this may throw some light on the preferential attack of the copper crystal by oxygen.

### Summary.

It is shown that an etching effect obtained on heating copper *in vacuo*, is due to the presence of cuprous oxide. The effect can be produced artificially by oxidising the surface and it is suggested that the etch is due to attack by oxygen along crystal planes similar to the action of any etching agent. The planes most readily attacked appear to be [100] and [110] planes of the copper crystal.

The relation between the orientation of the copper crystal and the cuprous oxide formed when copper is oxidised in the presence of a small quantity of air at low pressures was investigated. The first layer to be formed consists of small crystals arranged approximately in the same way as the copper. Subsequent layers take the form of a fibre structure in which a [110] direction agrees closely with the first layer and with a [110] of the copper crystal.

I wish to thank the Leverhulme Research Fellowship Committee for a grant in aid of this investigation. Professor C. E. Inglis, F.R.S., has very kindly allowed me to work in the Engineering Department of the University, and I am also indebted to Professor R. S. Hutton for special facilities in the Goldsmiths Metallurgical Laboratory, and to Dr. D. Stockdale for help on several occasions.

## THE SUBOXIDES AND SUBHALIDES OF CADMIUM.

By R. E. HEDGER AND H. TERREY.

*Received 13th August, 1936.*

In this work an attempt was made to prepare the subhalide by solution of cadmium in molten cadmium chloride and the suboxide by decomposition of the so-called subhalide by water. The products obtained were examined by means of their X-ray spectra. The analytical results agreed with those of Morse and Jones,<sup>1</sup> but the structures found were identical with those given by (1) the normal chloride and (2) normal oxide and metal. This is in harmony with results obtained by other physical measurements on the solid products, e.g., density, heats

<sup>1</sup> *Amer. Chem. J.*, 1890, 12, 488.

of solution, magnetic properties, etc., and it must be concluded that subhalides and suboxide are incapable of existence as solid phases.

**Experimental.**—Thermal analysis of the system Cd, CdCl<sub>2</sub>.

To carefully purified cadmium chloride rendered anhydrous in a stream of HCl gas increasing amounts of cadmium were added and the melting points of the resulting mixtures determined, a calibrated thermocouple being used. The melting was carried out in a fireclay crucible with a luted lid—a slow stream of CO<sub>2</sub> being passed through an aperture in the lid to prevent oxidation. The addition of cadmium was continued until the maximum depression of the melting-point was obtained. At the end of each determination samples were removed from the mass for analysis, which was carried out by a determination of the chlorine content. The results are tabulated above.

M. Pt.	Chlorine Content.		Mol. Per Cent. of Cadmium.
568°	---		0
558°	37.9	37.8	3.4
544°	36.8	36.9	7.7
530°	35.6	35.5	12.5

These results are in good agreement with those of Aten. The maximum depression 12.5 mol. per cent. of cadmium corresponds to the Morse and Jones compound Cd<sub>4</sub>Cl<sub>7</sub>. With greater cadmium content the mass separates into two phases—the saturated solutions of Cd in CdCl<sub>2</sub> and CdCl<sub>2</sub> in Cd.

FIG. 1.

**Solubility of CdCl<sub>2</sub> in Cd.**

This was determined by adding cadmium chloride to cadmium and finding the melting-point and composition of the mass. It was found only possible to dissolve 0.2 mols. per cent. of the chloride in the metal which lowered the melting-point from 322° C (M.Pt. of pure cadmium to 319° C. The two sets of results are shown graphically in Fig. 1.

**Investigation of the System Cd-CdCl<sub>2</sub> at higher temperatures.**

The experimental procedure in this case was to heat equal mixtures of cadmium and cadmium chloride in a sealed silica tube in an electric furnace to the required temperature. The tube was periodically shaken to ensure equilibrium being set up. At the end of the heating the tube was dropped into cold water in order that the solidified layers should have the same composition as when liquid. The two layers were separated, a clear division being obtained with ease, and each analysed.

The results are summarised in Table I. and also shown graphically in Fig. 1.

The figures below agree with those of Aten<sup>2</sup> up to his maximum temperature 633°. The discontinuity in the solubility is difficult of explanation. A similar effect was noted by Eggink<sup>3</sup> in the system Bi, BiCl<sub>3</sub> and there ascribed to the formation of a lower chloride. We were at first inclined to favour this view here. One, however, might reasonably expect that in the rapidly quenched mass some indications of the existence of a subchloride would be found. X-ray photographs of the mass from specimens above and below the point of discontinuity gave line spectra

TABLE I.—CADMIUM CHLORIDE—  
CADMIUM PHASE.

Temperature.	Per Cent. of Cl.	Mol. Per Cent. of Cd.
570	35.3	13.6
610	34.9	15.1
660	34.4	17.0
700	33.4	20.6
760	33.85	18.7
810	34.1	18.1

identical with that of the normal chloride. Although the photographs given by the quenched mass were hazy and not suitable for reproduction there was no difficulty in measuring the position of the lines and the thirty-two recorded agreed well within the experimental error with those of CdCl<sub>2</sub>. It is interesting to note that cadmium lines did not appear on these photographs, the metal being disseminated throughout the mass in a very finely divided state.

Increase in temperature had little effect on the solubility of cadmium chloride in cadmium, the chlorine content varying between 0.12-0.16 per cent. corresponding to a cadmium mol. per cent. content of 99.8-99.75.

#### Cadmium subhydroxide and suboxide.

The eutectic mixture—the so-called compound Cd<sub>2</sub>Cl<sub>3</sub>, was taken and washed repeatedly with water for 2 to 3 days until the washings were free from chlorine ions. The resulting mass which was of a dark grey colour was dried in a vacuum desiccator and analysed. Found: Cd 86.0, 86.1. Cd (OH) requires 86.9.

The above substance was then heated in a paraffin bath at 300°, a stream of dried nitrogen freed from oxygen by treatment with heated copper turnings being passed over the heated material. A dark yellow powder with all the reducing properties attributed to it by Morse and Jones was obtained. Analysis gave cadmium contents of 92.9 and 93.0 per cent., Cd<sub>2</sub>O requires 93.3 per cent.

Powder photographs of this mass were taken and compared with the normal oxide. As is evident from these the spacings and intensities of the two are identical and it must be concluded that the so-called suboxide is merely a mixture of the normal oxide and very finely divided metal.

#### Summary.

An attempt was made to prepare the suboxide and subhalide of cadmium. Although the analytical data agree fairly well with the formula given to the sub-compounds X-ray photographs of the products do not support this view. Data are given for the solubility of cadmium in cadmium chloride over the temperature range 570-810° C.

# THE PREPARATION AND PROPERTIES OF INDIUM DICHLORIDE.

BY J. K. AIKEN, J. B. HALEY AND H. TERREY.

*Received 19th August, 1936.*

Although the existence of indium dichloride has never been questioned, it has equally never been satisfactorily proved. The usual preparative methods yield a substance whose composition approximates to  $\text{InCl}_2$  but analyses vary considerably; and the reaction with water, the final products of which are metallic indium and the trichloride,<sup>1</sup> is very unusual in a halide. Also, from the position of indium in the Periodic Table the expected chlorides would be  $\text{InCl}$  and  $\text{InCl}_3$  and not  $\text{InCl}_2$  as such, although the latter might be considered as a loose molecular associate of the two stable chlorides. The vapour density evidence of Nilson and Pettersson<sup>2</sup> is inconclusive since the values obtained (at  $606^\circ \text{C}$ . obs. 8.15; calc. for  $\text{InCl}_2$  7.58) might equally well be produced by mixtures of  $\text{InCl}$ ,  $\text{InCl}_3$  and chlorine.

The customary method of preparation, *i.e.* by the action of dry  $\text{HCl}$  on metallic indium<sup>1,3</sup> has several disadvantages, *e.g.* if the slightest trace of moisture is present irreversible formation of  $\text{InCl}_3$  occurs and, in the presence of oxygen, the oxychloride  $\text{InOCl}$  is formed. Klemm,<sup>4</sup> using carefully controlled temperatures and in the presence of carbon dioxide, still found a tendency for the formation of the trichloride even at temperatures as low as  $420^\circ$ , while below  $320^\circ$  the chlorine content was too low (37.14 per cent. obs.; 38.18 per cent. calc.). Klemm<sup>4</sup> also examined the interaction of the metal and the trichloride as a possible preparative method and concluded that the liquid dissociates to some extent into the mono- and tri-chlorides:—

By the use of a mixture of hydrogen and  $\text{HCl}$  the presence of any traces of  $\text{InOCl}$  or  $\text{InCl}_3$  can be avoided. It was found that if the trichloride was heated in a stream of hydrogen in an apparatus similar to that used by Mathers<sup>5</sup> for the preparation of the trichloride, a gradual reduction to the metal took place; the stage  $\text{InCl}_3 \rightarrow \text{InCl}_2$  readily and quantitatively at about  $600^\circ \text{C}$  (just above the sublimation point of the trichloride) and the stage  $\text{InCl}_2 \rightarrow \text{InCl}$  with more difficulty at about  $700^\circ$ . The oxychloride, although only slowly affected by hydrogen alone, is readily attacked by a mixture of hydrogen and  $\text{HCl}$ .

If the mixture of gases contained rather less than 20 per cent.  $\text{HCl}$ , and the working temperature did not exceed  $600^\circ$ , the reduction was completely stopped at the dichloride stage. The complete absence of water and oxygen in the  $\text{HCl}$  (difficult to ensure) is now unnecessary since any formation of  $\text{InOCl}$  and  $\text{InCl}_3$  is precluded. Another advantage of this method is that the starting material need not be metallic indium, but may

<sup>5</sup> Mathers, *J. Am. Chem. Soc.*, 1907, 29, 495.

be the hydroxide or the trichloride, the latter probably being the better. The trichloride was prepared by the method of Mathers<sup>3</sup> from  $\text{In}(\text{OH})_3$ , which had been dried at  $100^\circ$ . The presence of iron chlorides colours the  $\text{InCl}_3$  yellow; these can be easily separated by fractional sublimation. The same apparatus was used for the reduction to the dichloride, it being possible to pass in pure dry  $\text{HCl}$ , hydrogen or nitrogen either together or separately. A slow stream of hydrogen containing about 15 per cent.  $\text{HCl}$  was passed over the  $\text{InCl}_3$ , while the tube was heated to low redness at the constriction. The dichloride collected as a yellow liquid in the second bulb and was gradually distilled along the tube in the same gaseous mixture. It was then heated just above its melting-point in a slow stream of nitrogen for about  $\frac{1}{4}$  hour to remove  $\text{HCl}$ , allowed to cool and sealed off.

The final product was a white glassy solid melting *sharply* to a very pale yellow liquid, which solidified equally sharply. The melting-point, measured in an atmosphere of nitrogen with a micro-thermocouple (copper-constantan in a Pyrex capillary), was  $235^\circ \pm 1^\circ \text{C}$  and the boiling-point approximately  $570^\circ \text{C}$ .  $\text{Cl}$  found = 38.07 per cent.; theoretical value, 38.19 per cent.  $\text{In}$  found = 61.60 per cent.; theoretical value, 61.81 per cent.

In the liquid phase there is some tendency for the dichloride to dissociate into the mono- and tri-chlorides; this dissociation is also produced by the action of water (*cf.* indium dibromide) followed by the decomposition of the monochloride into indium and the trichloride. Indium oxychloride and trichloride are produced by the action of steam, while moist air produces the metal in addition to these compounds. If the dichloride is heated strongly in moist air,  $\text{InOCl}$  and  $\text{InCl}_3$  are first produced, and at higher temperatures the oxychloride decomposes to  $\text{In}_2\text{O}_3$  and  $\text{InCl}_3$ .

A striking feature of the properties of indium dichloride is its strong resemblance in physical properties to anhydrous stannous chloride (first mentioned by Klemm)<sup>4</sup> *viz.* :—

Crystallographic data (see X-ray section).	Orthorhombic. $b_0 = 9.64 \pm 0.06 \text{ \AA}.$ $a : b : c = 0.710 : 1 : 1.093$	Orthorhombic. $b_0 = 9.34 \pm 0.04 \text{ \AA}.$ $a : b : c = 0.708 : 1 : 1.069$

\* Klemm<sup>4</sup> also gives 3.64. † Klemm gives 3.95. ‡ Klemm gives  $235^\circ$ .

In this connection it is noteworthy that the specific conductivities of the fused substances are unequal; that of stannous chloride being considerably greater than that of indium dichloride.<sup>4</sup> This similarity gives weight to the supposition that, in the solid state, the dichloride is a definite compound. Since it seemed possible that the two solids might be isomorphous an X-ray examination of the pure chlorides was undertaken.

**Preparation of Anhydrous Stannous Chloride.**—Commercial  $\text{SnCl}_4 \cdot 2\text{H}_2\text{O}$  was heated in a pyrex distillation apparatus in a stream of dry  $\text{HCl}$  until frothing ceased. It was then distilled over, collected and redistilled in the same apparatus. The distillate was kept just above its melting-

point, first in dry HCl and then in dry nitrogen and finally poured off and stored in a vacuum desiccator over  $P_2O_5$ .

**Density Measurements.**—The densities of the solid chlorides were measured in dry nitrobenzene which had been stood over anhydrous sodium sulphate and distilled three times. The mean of several determinations gave 3.90 for stannous chloride and 3.64 for indium dichloride.

**X-Ray Technique.**—Although crystallographic measurements of anhydrous stannous chloride have been reported by Nordenskjöld<sup>8</sup> who stated that the crystals belong to the orthorhombic system with  $a : b : c = 0.7366 : 1 : 1.068$ , many attempts in this present work to obtain satisfactory single crystals have been unsuccessful, *e.g.* (a) by sublimation both above and below the melting-point of the chloride (the former in vacuo); (b) by crystallisation from many solvents such as absolute alcohol, ether, benzene, *o*-dichlorobenzene and thionyl chloride; very small clusters of crystals were obtained from absolute alcohol but it was impossible to separate out any single crystals; (c) by the hot-wire method of Bernal and Crowfoot.<sup>9</sup> As no direct experimental details of the method employed by Nordenskjöld were available, his method for the preparation of a single crystal could not be attempted and thus the X-ray analyses could only be carried out on powdered samples of the chlorides.

Similarly it was not found possible to obtain single crystals of indium dichloride by any of the above methods.

### Experimental.

The specimens were ground in a desiccator over  $P_2O_5$ . During the exposure, the indium dichloride specimens were supported in thin Lithia glass tubes (0.5 mm diameter) which were sealed at both ends. These tubes were used in order to prevent any possibility of the dichloride taking up water during the exposure with its subsequent decomposition.<sup>4</sup> Again for the same reason the exposures were completed as rapidly as possible by using a small diameter camera; the exposure time being about 20 minutes. This limits the accuracy of the ultimate lattice constants but the photographs were poor and the object of the work is more to show the similarity of the two substances rather than the precision determination of the lattice constants. The stannous chloride specimens were supported in thin collodion tubes (0.5 mm. diam.) and photographed in a larger diameter camera as the danger of decomposition is not nearly so great as with indium dichloride. The glass tubes were found to be unsuitable in this case owing to the production of a very high background density.

Cu  $K\alpha$  radiation was used for the final experimental work. Mo radiation was tried in the preliminary experiments and produced clearer photographs but the lines were too close for measurement (even when filtered with zirconium oxide). Fe radiation produced photographs whose density was too great for any measurements to be attempted. In all cases dilution of the specimens with pure dry starch (*cf* Davey)<sup>10</sup> had little or no effect.

Pure, dry sodium chloride was used for calibration purposes and was separated from the main sample by means of a plug of cotton wool.

In all cases the strictest precautions were taken to prevent the entrance of moisture during the grinding and exposures of the samples.

The specimens were oscillated through a  $10^\circ$  arc during the exposures. The values of the reflection angles, in angular measure, were averaged from the separate films (two for indium dichloride and three for stannous chloride).

All the resulting powder photographs were very poor, possessing a high background density making measurement difficult and for these reasons

<sup>8</sup> Nordenskjöld, *Bihang. K. Sv. Vet-Akad. Handl.*, 1874, 2, no. 2.

<sup>9</sup> Bernal and Crowfoot, *Trans. Faraday Soc.*, 1933, 29, 1032.

<sup>10</sup> W. P. Davey, *Study of Crystal Structure and its Applications* (New York), 1934, p. 118.

the visual intensities reported in the tables must be treated with caution. It was found possible to measure with certainty 17 lines for indium dichloride and 16 lines for stannous chloride; only those lines whose existence on either side of the centre was in no doubt have been used in the calculations.

The calculated values of  $d$  for both the chlorides were found to fit the same logarithmic plot for orthorhombic crystals<sup>11</sup> at the approximate axial ratios  $a:b:c = 0.71:1:1.1$  from which the indices marked \* in tables were obtained. The calculated values of the lattice constants obtained from these indices were utilised to index the remaining planes which could not be indexed directly from the plot owing to its complexity at low values of  $d$ .

For orthorhombic crystals the quadratic form for each reflection, assuming zero errors, is:—

$$A_0 \cdot h^2 + B_0 \cdot k^2 + C_0 \cdot l^2 = \sin^2 \theta$$

where:  $A_0$ ,  $B_0$  and  $C_0$  are respectively  $\lambda^2/4a_0^2$ ;  $\lambda^2/4b_0^2$ ;  $\lambda^2/4c_0^2$ .

The observation equations for each reflection were combined, by Gauss's method,<sup>12</sup> yielding three normal equations which were solved, by determinants, for  $A_0$ ,  $B_0$  and  $C_0$ †:—

$$A_0 \Sigma h^4 + B_0 \Sigma h^2 k^2 + C_0 \Sigma h^2 l^2 = \Sigma h^2 \sin^2 \theta$$

$$A_0 \Sigma h^2 k^2 + B_0 \Sigma k^4 + C_0 \Sigma k^2 l^2 = \Sigma k^2 \sin^2 \theta$$

$$A_0 \Sigma h^2 l^2 + B_0 \Sigma k^2 l^2 + C_0 \Sigma l^4 = \Sigma l^2 \sin^2 \theta$$

Density for 8 molecules of  $\text{SnCl}_2$  or 4 molecules of  $\text{Sn}_2\text{Cl}_4$  = 4.00.  
Experimental density = 3.90.

The deviation of the theoretical densities from the experimentally measured values, for both the chlorides, lies within the experimental error of the lattice constant determinations. When comparing the above experimental axial ratios for stannous chloride with those given by Nordenskjöld,<sup>1</sup> it must be remembered that although, in his paper, the figures are stated to be only approximate they are given to 4 decimal places; in addition the author appears to be in doubt as to the purity of his sample.

It should be noted that seven preparations of indium dichloride and five of stannous chloride yielded identical powder diagrams; the latter including a preparation by the action of dry HCl on metallic tin.

The preparation and analysis show that, in the solid state, indium dichloride is a definite chemical entity and this is confirmed by the X-ray evidence. Its very close resemblance to anhydrous stannous chloride shows that it cannot be a "molecular" compound of the residual valency type. That this resemblance to some extent persists in the liquid phase is shown by the similar, but by no means equal, specific conductivities and boiling-points.

It is now reasonable to assume that the vapour density values of Nilson and Pettersson<sup>2</sup> are actually due to the presence of associated molecules of  $\text{In}_2\text{Cl}_4$ , more particularly so since this effect is also observed with stannous chloride.<sup>14</sup> The solids are no doubt completely associated to compounds of the type  $\text{M}_2\text{Cl}_4$ , as in the case of anhydrous cupric chloride and other anhydrous metallic chlorides. The fact that molecular weight determinations of stannous chloride in organic solvents<sup>15, 16</sup> indicate that it exists as single molecules cannot be taken

<sup>14</sup> Biltz and Meyer, *Ber.*, 1888, 21, 22.

<sup>15</sup> Werner and Schuler, *Z. anorg. Chem.*, 1897, 15, 1.

<sup>16</sup> N. Castoro, *Gazz. Chim. Italiana*, (ii), 1898, 28, 317.

as evidence for the molecular condition of the solid (*cf.* for example molybdenum dichloride, which is trimolecular in the solid<sup>17</sup> although unimolecular in urethane; <sup>18</sup> the latter being one of the solvents used for the molecular weight determination of anhydrous stannous chloride).<sup>18</sup> Stannous chloride (*cf.* cupric chloride) is probably derived from  $\text{H}_2\text{SnCl}_4$  with the following structure :

Similarly indium dichloride is probably derived from  $\text{HInCl}_4$  :—

These structures, although differing in ionic charges, have identical electronic configurations, which would lead to strong physical similarities between the two chlorides. The larger ionic charge of anhydrous stannous chloride would also account for its greater conductivity in the fused state.<sup>4</sup>

It may be supposed that these complex ions are relatively unstable, being decomposed by solvents and partly dissociated on fusion (more particularly so on vaporisation). The breakdown of the complex  $\text{SnCl}_4^{--}$  ion will lead to the formation of  $\text{Sn}^{++}$  and  $\text{Cl}^-$  ions, *i.e.* simply ionised  $\text{SnCl}_2$ , *viz.* :—

while that of the  $\text{InCl}_4^-$  ion will give  $\text{In}^+$ ,  $\text{In}^{+++}$  and  $\text{Cl}^-$  ions, *viz.* :—

The above reactions provide a logical explanation of the action of water and heat on indium dichloride. The yellow colour of the fused chlorides can then be explained by the presence of small quantities of stannous chloride ( $\text{SnCl}_2$ ) and indium monochloride respectively. This is supported by the observation that if indium dichloride is heated in a sealed, evacuated tube (*i.e.* under conditions favourable to this dissociation) and suddenly cooled, the solid is coloured yellow or red.

We wish to point out that the suggested structures are based on chemical rather than X-ray evidence.

### Summary.

A new method for the preparation and the chief properties of indium dichloride are described.

This substance is shown to be similar in physical properties to anhydrous stannous chloride. X-ray analysis shows both substances to belong to the orthorhombic system with similar lattice constants.

Evidence is presented to support the view that both substances are associated in the solid state.

# THE INTERACTION OF CARBON DISULPHIDE AND SULPHUR DIOXIDE.

BY B. CRAWLEY AND R. H. GRIFFITH.

*Received 8th September, 1936.*

The fact that carbon disulphide reacts with sulphur dioxide, in contact with alumina, to give carbon dioxide and sulphur, has been recorded by Lenander.<sup>1</sup> A survey has now been made of a wide range of catalysts for this reaction.

The apparatus employed is shown in Fig. 1. A stream of sulphur dioxide was measured by the flow gauge A, and passed over carbon disulphide in the saturator B, which was kept at any desired temperature in a thermostat. The mixture then entered the reaction tube made of

FIG. 1.—Apparatus for catalytic reaction between  $\text{CS}_2$  and  $\text{SO}_2$ .

Monel metal and heated in the electric furnace C. The lower end of this tube was also heated so that molten sulphur ran out of it into the collector D, which consisted of a glass vessel having a detachable metal head and containing a beaker of convenient size in which the solid product could be weighed. The system was freed from air by means of a stream of nitrogen entering at E. Comparative tests with various catalysts were carried out at  $450^\circ$  and atmospheric pressure by determining the weight of sulphur formed in 1 hour with a rate of 80 c.c. of sulphur dioxide per minute. The results were expressed as the weight of sulphur which would be given by

<sup>1</sup> U.S. Pat. 1,904,482, 1,904,483, *Brit. Chem. Abstr.*, B, 1934, 145.

shown by velocity curves given in Fig. 6. It is clear that Van der Waals' adsorption also takes place simultaneously, but owing to the overlap of the two types it was found impossible to separate one from another.

FIG. 6.—Adsorption velocity curves for  $\text{SO}_2$  on titanium sulphide.

### Discussion.

The feature of particular interest in this reaction is that activated adsorption of only one reactant is shown to be necessary. It is also evident that this type of adsorption first has a measurable velocity at just the same temperature as the reaction is detectable. The change therefore appears to occur by collision of a free carbon disulphide molecule with an adsorbed sulphur dioxide molecule.

It is intended to investigate the kinetics of this reaction more closely.

The facts now presented have also some significance with relation to the hydrogenation of carbon disulphide to give methane and hydrogen sulphide. Titanium sulphide is one of the most active catalysts for this reaction, at  $400\text{--}450^\circ$ , and the change therefore occurs similarly by collision of carbon disulphide with adsorbed hydrogen. It has been found that activated adsorption of hydrogen takes place on titanium oxide (unpublished data) and it must be presumed that it occurs equally on the sulphide.

# THE KINETICS OF SIMULTANEOUS POLYMERISATION AND RING FORMATION.

(A note in reply to Dr. Stoll.)

By. G. SALOMON.

Received 14th August, 1936.

A paper of the author's on this subject<sup>1</sup> occasioned some criticism.<sup>2</sup> The paper consisted of a survey of research results, without the inclusion of experimental details, and the kinetic analysis, being one in common use, was represented on this occasion only by some simple differential equations. A part of the author's experimental results have now been published in detail<sup>3</sup> and in this lengthy publication the points on which misunderstanding had arisen have been clarified.<sup>3</sup> They may be briefly summarised :

(1) Dr. Stoll does *not* discuss the constant of a first order reaction but that of a run made at one concentration only ; this is not permissible.<sup>4</sup>

(2) The enhanced reactivity of the imines is not " unsupported by experimental data " but was made very probable by the experimental results, which conform with the differential equations. The " schematic " example is calculated by Stoll with arbitrarily chosen constants, though Ostwald<sup>5</sup> showed long ago that the position of the turning point depends on the *ratio* of these constants

(3) Conclusions as to uncatalysed and irreversible imine-formation, if deduced from the kinetics of the catalysed, autocatalysed and reversible lactone-formation (esterification), are not possible on account of the difference in dimensions.

(4) In the determinations of yields by Stoll following the progress of the syntheses titrimetrically, water, which participates in the reaction and the presence of which is necessary for catalysis, is discontinuously distilled away.

(5) Determinations of yields in lactone-syntheses were calculated by Stoll with an unproved integral and comparisons carried out with the " constants " so obtained. This is at variance with the axioms and definitions of chemical kinetics. Moreover the arbitrarily established differential equations are applicable not to esterifications but to uncatalysed and irreversible reactions. If, however, the comparison of yields is carried out without the aid of mathematical apparatus, it has been proved, table 24,<sup>3</sup> that the polymers isolated *originate in different reaction-courses, four different esterification-reactions being possible*. This result is in good agreement with the researches of Carothers<sup>6</sup> and the predictions of Ziegler.<sup>7</sup>

## THE RAPID MEASUREMENT OF THE OXIDATION OF INSULATING OILS IN AIR.

BY A. GEMANT.

*Received 13th July, 1936.*

The author recently investigated<sup>1</sup> the absorption of air by mineral oils for a temperature range of 20° to 80° C. The method used was a manometric one, and it seemed obvious that a similar apparatus could be used for the determination of the tendency of an oil to oxidise at higher temperatures. Although a certain amount of work exists already on the subject of oil oxidation,<sup>2</sup> the results so far obtained have not been completely conclusive and it was decided to carry out further experiments on this line which are here recorded.

It is generally agreed that the oxidation rate of an oil is not an absolutely reliable measure of its stability in practical service: coking tests, measuring carbon deposits, or sludge tests are generally preferred as laboratory methods. The British Air Ministry makes use of the change in viscosity after a prolonged treatment<sup>3</sup> in its test for lubricating oils. Weiss and Vellinger<sup>4</sup> consider the change of different physico-chemical factors after an artificial ageing much more important than the actual measure of oxygen absorption.

There exist, however, several methods for testing an oil by its actual oxidation rate. Mardles<sup>5</sup> and Ornstein and collaborators<sup>6</sup> determine

the absorbed oxygen by chemical analysis; Evers and Schmidt<sup>7</sup> by the number of coulombs necessary to replace the loss by electrolytic oxygen, while Evans<sup>8</sup> makes use of the simple manometric method.

The two chief advantages of the test described below are its simplicity and its quickness, it being possible to complete one in approximately two hours. Although a more prolonged test certainly yields results more in accord with the actual behaviour in service, cases often arise where, for some reason or other, a quick estimation of the quality of the oil is required.

### The Method and Apparatus.

If oil is kept in a closed space at a high temperature and constant pressure, the progressing oxidation can be measured by means of a manometer indicating the steadily decreasing volume of the gas above the oil. Such measurements are rather unsuitable for chemical investigations since the decrease in volume is really the algebraic sum of two terms, the positive terms being given by the volume of oxygen absorbed by the oil and the negative one by the volume of volatile gases formed as a result of the oxidation of the oil. But since our present purpose is only to find some characteristic difference between oils of different quality, it does not matter much whether the results are fit for chemical analysis or not.

FIG. 1.—Diagram of oxidation apparatus.

In order to obtain quick changes in the volume of the air, the latter was chosen to be of the same order as that of the oil in contact with it, in contradistinction to the arrangement of other experimenters, using a much larger volume of air than of oil. In any case the change in volume cannot be directly interpreted as a rate of oxidation, since the decrease of the concentration of oxygen in the gas phase has to be taken into consideration. In a comparatively short time equilibrium between oil and gas will be reached and the whole process stops. This on the other hand is not a disadvantage, so long as the process itself is really different for oils of differing grade.

The apparatus used is shown diagrammatically in Fig. 1; A is a glass bulb of some 200 c.c. content, filled with 130 c.c. of the oil to be measured. B is a ground-glass joint, leading to the three-way stopcock C. The tube D serves for cooling the upper part by continuously running water, thus

<sup>7</sup> F. Evers and R. Schmidt, *Erdöl und Teer*, 1933, 9, Nos. 1 and 2.

<sup>8</sup> E. A. Evans, *World Petrol. Congress*, London, 1933, 2, 460.

keeping the joints tight during heating. The whole was mounted on the board E and shaken, if required, by the arm F of a shaking device. G is an oil bath, with electric heaters I and I' and a thermometer J. The tubing K leads to a pump and the tubing L by means of the stopcock P, to a manometer with two separate branches M and O joined by the tubing N. Q is a calcium chloride tube to keep the system dry.

Readings are taken by shifting the right branch of the manometer, until both are level. The volumes given in the following graphs are always reduced to normal conditions ( $0^{\circ}$  C. and 760 mm. Hg pressure), and to 100 gm. of oil.

### Results for Constant Temperature.

The best results can be obtained by keeping the temperature at a certain constant value, and plotting curves relating changes in gas volume to time. In Figs. 2 and 3, the decrease in volume is measured in c.c.,

FIG. 2.—Oxidation curves for four oils at  $155^{\circ}$  C. (reduced c.c. of gas against mins.).

and the time in minutes. Each figure contains data for four special oils at  $155^{\circ}$  and  $145^{\circ}$  C. respectively. Copper catalyst was always present.

In this paper only thin oils of the insulating type are considered, but the extension of the method to other oils, for instance lubricating oils, is certainly feasible. A few

FIG. 3.—Oxidation curves for four oils at  $145^{\circ}$  C.

In comparing the results for the four different oils, consider first the  $155^{\circ}$  curves (Fig. 2). A 30 and A 0 show a rapid absorption, which suddenly stops, the change afterwards being a slight decrease for A 30, a slight increase for A 0. B 30 shows rapid absorption first, which is soon

TABLE I.—DATA OF OILS.

Number.	Grade to British Standard Specification.	Origin.	Sludge Fig. per Cent.
1	A 30	Russia	0.02
2	A 0	America : Kansas, Oklohama	0.05
3	B 30	Russia	0.21
4	B 0	America : Eastern Pennsylvania	0.53

replaced by a slower process, finally stopping like the other two. B 0 exhibits only the first rapid absorption which stops very soon, the curve slightly decreasing further.

Although it is not possible to draw definite conclusions without a more detailed work (chemical analysis of the gas), it is still evident that the aspect of the curve is strikingly different for oils of different grade.

FIG. 4.—Repeated curves for a sample of A 0 oil at 155° C. (in intervals of 3 days).

Summarising the differences we could say that the steeper the curve and the higher the ordinate which it finally reaches, the higher the quality of the

FIG. 5.—Repeated curves for B 0 oil at 145° C.

oil. This somewhat paradoxical result may be accounted for by the fact that the less stable the oil, the further oxidation proceeds and the more likely the formation of volatile, low molecular end products, *e g.*, acids, which counteract the decrease of the gas volume. A gas-analysis after the oxidation is finished, would show whether this assumption is right. Hence the range of the

four oils is : A 0, A 30 (both very nearly the same) ; B 30, B 0 in good agreement with the sludge figures.

The difference between the curves in Fig. 3 (for  $145^{\circ}\text{C}.$ ) still exists on similar lines, although it is somewhat blurred by induction periods exhibited by the A grade oils. It must be remembered (and will be shown later) that the above behaviour for  $155^{\circ}\text{C}.$  is reversed at lower temperatures (below  $140^{\circ}\text{C}.$ ), where the volume changes are the more pronounced the less stable the oil, since in this temperature range the curves are controlled mainly by the absorption rate of oxygen. It follows, therefore, that the above striking difference is best exhibited at temperatures very near  $150^{\circ}\text{C}.$ , since at still higher temperatures (above  $160^{\circ}\text{C}.$ ) the production of volatile products probably dominates the process for any type of oil.

### Repeated Measurements with a given Sample.

The above result can be completed by repeating the same process on the same given sample of oil. Fig. 4 shows the result for the A o oil at  $155^{\circ}$ ; Fig. 5 for the B o oil for  $145^{\circ}\text{C}.$ , the curves being taken at intervals of 2-3 days. The high-quality oil shows the same type of curve at each repetition, with the final height, however, continuously decreasing. Even in this case volatile products are formed, which slightly increase with

FIG. 6.—Curves of oxidation at  $155^{\circ}\text{C}.$  with immediate repetition (at times indicated by arrows).

time. (The first total decrease seems to correspond quantitatively to the amount of oxygen existing in the bulb.)

The B o oil on the other hand yields quite different curves at each repetition (Fig. 5), and clearly, at the third time, one entirely on the negative side, showing a predominance of gaseous oxidation products over the oxygen absorbed.

A rather instructive comparison is shown in Fig. 6, including data for oils Nos. 1, 3 and 4 at  $155^{\circ}\text{C}.$  After 60 minutes shaking, the bulb was brought to rest, rapidly exhausted by means of the pump (no change

in physical absorption takes place during a few seconds with the oil at rest), and fresh air let in. Then shaking began and after 15 minutes the same procedure was repeated. Whereas the character of each repeated curve remains unchanged, so far as the A oil is concerned, there is a marked drop at the beginning of each new portion in the case of the B o oil.

### Curves with Varying Temperature.

Finally, Fig. 7 shows the rate of change of volume plotted against temperature for all four oils. The ordinates are the logarithms of (reduced) c.c. of gas per minute, the abscissæ temperature.

By a reasonable extrapolation of the curves beyond their measured range, it is seen that below say 140° C. the B grade oils lie above the A grade oils, whereas above say, 150° the opposite is the case. A rapid test below 140° is, however, not feasible, since the oxidation rate is generally so low that the change in gas volume would not become obvious enough in a short time. Hence our choice of 155° C.

FIG. 7.—Oxidation rate against temperature for four oils.

Hence our choice of 155° C.

### Conclusions.

The results indicate clearly that there is a marked difference in these oxidation curves concerning oils of different quality. Further comparative study with more samples and measurements, showing the correlation between this test and some other chemical changes in the oil, e.g., acid rise, sludging, peroxide formation, etc., will, however, be required to determine whether the method is really suitable for a routine test. It seems as if the chief merit of the test consists in a quick elimination of quite unsuitable types, whereas a further differentiation of the remaining good ones has to be carried out by one of the more prolonged tests. At any rate, the manometer could be replaced by an automatic pressure recorder, in which case the operation of the device, now at constant volume, could be made extremely easy. It is intended to continue the investigation on the lines just mentioned.

### Summary.

If oil is oxidised at about 150° C. under constant pressure in a relatively small closed space, and the decrease of the volume of the gas phase is plotted against time, curves are obtained which vary characteristically with the grade of the oil. The changes are the less pronounced, the curves the flatter, the poorer the oil, owing probably to production of volatile products, counteracting the effect of absorption of oxygen.

The method seems to be suitable for rapid testing of the stability of oils.

The author is much indebted to Professor R. V. Southwell, F.R.S., for facilities placed at his disposal; to Messrs. Metropolitan Vickers Electrical Co. Ltd., Manchester, for a grant enabling him to undertake this investigation; and to Messrs. Silvertown Lubricants for the samples of oil.

# THE CHEMICAL KINETICS OF DIELECTRIC RELAXATION.

BY F. C. FRANK.

*Received 13th August, 1936.*

When one says, on the grounds of its dielectric behaviour, that a cetyl palmitate molecule in solid solution in paraffin wax rotates about as freely as if it were in a continuous fluid of the viscosity of castor oil, that is useful in enabling one to feel in imagination the restraint upon the molecule, but in the end one must admit that the model is too remote from the actual conditions to be more than a helpful analogy. We have tried in the past to defend the model by supposing the ester grouping sufficiently incompatible with the hydrocarbon crystal to break it up in its immediate neighbourhood into a disordered condition approaching that of an oil: but this defence will not stand. That there can be no laminar flow is but one of many difficulties in the way of it. For example, when we change to butyl stearate instead of cetyl palmitate we find the maximum of dielectric loss at 7 MC. shifted down some  $44^{\circ}$  C in temperature. Taking a temperature coefficient of "viscosity" from the cetyl palmitate results, we find this corresponds to a change by a factor of 50. Yet neither the molecular volume nor any molecular dimension has been reduced by such a factor. The temperature coefficient is also different, and different again for a solid solution of cetyl alcohol in the wax. Thus we learn that both the "viscosity" and its temperature coefficient depend on the solute as well as upon the solvent.

It is clear that when we are applying the conception of viscosity to the movements of a single molecule, we must examine the discontinuous molecular processes which produce viscosity. Several theoretical discussions of viscosity <sup>1, 2, 3, 4</sup> are suggestive, though none is quite directly applicable to our case. We must go to something more fundamental than these, to which they are related, the theory of unimolecular reactions.

When electric stress is applied to some materials containing polar molecules a statistical departure from random orientation is impressed upon them. If the stress is abruptly removed, the impressed orientation, which is observable as an electric displacement within the material, decays with a finite relaxation time. This decay has hitherto been treated as a rotational diffusion by Brownian movement: but it is equally analogous to a *cis-trans* isomerism. The proposal of the present paper, therefore, is to apply the equations of chemical unimolecular reaction to the process of dielectric relaxation.

In practice we do not adopt the difficult expedient of abruptly removing an electric stress, but apply a sinusoidally alternating voltage to the material. Then for periods of alternation near to the relaxation time  $\tau$  for orientation of the polar molecules, we find an energy absorp-

<sup>1</sup> J. Frenkel, *Z. Physik*, 1926, **35**, 664; *Nature*, 1930, **125**, 581.

<sup>2</sup> J. S. Dunn, *Trans. Faraday Soc.*, 1926, **22**, 401.

<sup>3</sup> E. N. da C. Andrade, *Phil. Mag.*, 1934, **17**, 497, 698.

<sup>4</sup> H. Eyring, *J. Chem. Physics*, 1936, **4**, 283.

tion in the material and a dispersion of its dielectric constant: the dielectric constant passes through its mean value and the imaginary dielectric constant (which is a measure of the absorption) through its maximum when the period of alternation is approximately  $2\pi\tau$ . (See Fig. 1a.)

Debye introduced an inner friction constant governing molecular rotation in his treatment of the relaxation (ref. 5, p. 85). Tentatively he estimated this by the Stokes' formula for rotation of a sphere in a viscous fluid, obtaining

$$\tau = \frac{4\pi\eta a^3}{kT}$$

(where  $\eta$  is viscosity,  $a$  molecular radius,  $k$  Boltzmann's constant.), to connect  $\tau$  with at least a reasonable order of magnitude for the molecular radius. The success with hydroxylic liquids was unexpectedly good, but since then more normal systems have all shown excessively small radii. The maximum loss for these liquids occurs, however, in a highly inaccessible range of frequency, and the best examples of the Debye loss curves have been found with solids or semi-solids to which this formula can only be applied by introducing an entirely fictitious viscosity.

We shall not be able to distinguish in practice (at least, with present resources) between the Brownian rotation and chemical reaction mechanisms. According to the former, the molecule loses the impressed orientation by a succession of random movements, the trace of its original position becoming less and less after each. According to the latter, the molecule is supposed to make larger and less frequent movements, one of which destroys practically all trace of the original orientation (at other times oscillating about a temporarily fixed mean position). There will be very little difference when we observe the integrated effect of many

FIG. 1.—Theoretical variation of dielectric constant ( $\epsilon'$ ) and loss ( $\epsilon''$ ). (a) with frequency and (b), (c), with temperature.

For (b),  $\log_{10} \tau$  is assumed to change by 1 for  $10^{\circ}$  change of temperature, and  $\epsilon_1$  is given a temperature variation shown by the broken curve as an ideal case of orientation polarisation.

In (c) the  $\epsilon''$  curve of (b) is redrawn on a logarithmic scale. The symmetrical broken curve corresponds to a constant  $\epsilon_1$  or the  $\epsilon''$  curve of (a).

molecules. Moreover, there will be no sharp borderline distinguishing systems to which one or the other treatment should be applied, though we can often say which is the appropriate treatment in particular cases. When the polar solute molecule is much larger than the molecules of solvent the Brownian movement treatment is applicable. Where we have a molecule of variable orientation embedded in a crystalline solid (as for example our solid solution of cetyl palmitate in paraffin wax), the unimolecular transformation treatment is fairly evidently more suitable. This is also the natural corollary of the special treatment tentatively suggested by Debye for ice (ref. 5, p. 104).

In the simplest sort of case, we should suppose the polar molecule undergoing rotational oscillations with a certain frequency  $\nu$  about a fixed mean position, until it received (as a thermal fluctuation) enough energy of oscillation  $\epsilon$  to lift it over a potential barrier, when it would have the chance to settle down into other minima of potential energy with different orientations. In such a case the activation would be in two quadratic terms, and the rate of the de-orientation reaction would be

$$2\nu e^{-\epsilon/kT},$$

since the attempt to leave the potential valley can be made twice in each vibration, while the probability of success is given by the Boltzmann term. This is analogous to Frenkel's viscosity theory, and the simplest class of chemical reactions: but it makes the supposition that the environment of the molecule is permanent and unvarying, whereas in reality it will also be subject to thermal fluctuations. Hence we may anticipate in some cases at least the more complicated behaviour characteristic of activation in many degrees of freedom, producing in this case a general loosening of the material in the neighbourhood of the polar molecule. Since the limits of the system here include the whole crystal, whereas in the majority of unimolecular chemical reactions it is only a molecule of a hundred atoms at the most, we may anticipate extreme values of the number of degrees of freedom activated, providing an interesting extension to the class of unimolecular reactions. The effects of activation in many degrees of freedom are to produce large values both of  $C$  and  $A$  in the Arrhenius equation

$$k = Ce^{-A/RT}.$$

Debye represented the decay of orientation as a simple exponential process

$$\phi(t) = e^{-t/\tau}$$

$t$  being time,  $\tau$  the relaxation time (ref. 5, p. 84), so that when we represent it as a unimolecular reaction the velocity constant must be taken as  $1/\tau$ . Using this expression Debye deduced the following equations defining the behaviour in an alternating field:

$$\epsilon' = \epsilon_0 + \frac{\epsilon_1 - \epsilon_0}{1 + x^2}$$

$$\epsilon'' = \frac{\epsilon_1 - \epsilon_0}{1 + x^2} x$$

where

$$x = \frac{\epsilon_1 + 2}{\epsilon_0 + 2} \omega \tau,$$

$\omega$  is the circular frequency,  $\epsilon_1$  the dielectric constant at low frequency,  $\epsilon_0$  that at high frequency,  $\epsilon'$  and  $\epsilon''$  the real and imaginary parts of the complex dielectric constant  $\epsilon^*$

$$\epsilon^* = \epsilon' - i\epsilon''$$

(Fig. 1a).

There is experimental evidence that  $\log \tau$  varies nearly linearly with temperature. This is equally in harmony with the temperature variation of viscosities and of velocity constants. When the temperature coefficient of  $\tau$  is large, as in the experimental cases considered in this paper, we may neglect other sources of variation with temperature (chiefly the change of  $\epsilon_1 - \epsilon_0$ ), and attribute all the temperature variation at constant frequency of  $\epsilon'$  in the range of maximum dispersion, and  $\epsilon''$  throughout its measurable range, to the change of  $\tau$ : as a result, the change of these quantities with temperature is closely similar to their change with the logarithm of the wave-length. (Fig. 1b.)

### To Derive $\tau$ and its Temperature Coefficient from Loss Measurements.

In an ideally simple case in which  $\log \tau$  is a strictly linear function of the temperature  $T$ , and  $\epsilon_1$ ,  $\epsilon_0$  and  $\omega$  constant, the graph of  $\log \epsilon''$  against  $T$  becomes a hyperbolic curve approximating closely, except near the apex, to a pair of straight lines of equal and opposite slope (Fig. 1c). The slope of these asymptotes is  $\frac{d}{dT} \log \tau$ . The same is true of the asymptotes of the logs of power factor, dipole conductivity, and in fact all the quantities in terms of which dielectric loss is specified. This is one of the most valuable relations for deriving the required information from experimental results, since it can be applied if necessary to results measured at only a single frequency. The method of logarithmic plotting against temperature is also a much more sensitive test of departure from ideal behaviour than the usual direct plot. Its only disadvantage is that it throws reliance upon measurements of the dielectric loss away from the maximum, where it may be very small. There will be some tendency to underestimate the temperature coefficient when there are not enough accurate points sufficiently far from the maximum.

Where it is necessary to deal with measurements near to the maximum, the ideal loss curve can be described to a sufficient approximation by

$$\frac{\epsilon''}{\epsilon''_{\max.}} = y = \frac{2e^{\alpha/T_m}}{1 + e^{2\alpha/T_m}}$$

when

$$\tau = k_1 e^{\alpha/T} \approx k_1 e^{-\alpha/T_m}$$

so that

$$\frac{d}{dT} \ln \tau = -\frac{\alpha}{T^2},$$

$t$  is  $(T - T_m)$ , where  $T_m$  is a temperature in the middle of a small range—here the temperature at which  $\epsilon''$  is maximum.

The same formula applies to dipole conductivity, and in the special case of a dilute solution of polar solute in non-polar solvent (which in any case is the only one in which ideal behaviour can be expected), also to the power factor and related quantities.

From this expression we obtain

$$e^{\alpha t/T_m^2} = \frac{1}{y} \pm \sqrt{\frac{1}{y^2} - 1}$$

and

$$dy/dt = \frac{2\alpha}{T_m^2} \cdot \frac{e^{\alpha t/T_m^2} - e^{3\alpha t/T_m^2}}{(1 + e^{2\alpha t/T_m^2})^2},$$

whence it is possible to derive expressions for the width of the curve ( $t_2 - t_1$ ), or its slope for any particular value of  $y$ . The use of these quantities should, however, be avoided when possible, since any sort of inhomogeneity in the material, which is to be anticipated in all cases for which extensive measurements near the loss maximum have yet been made, causing  $\tau$  to have not a single value but a small range, will lead to serious underestimates of the temperature coefficient of  $\tau$  by this method. Another objection to it is that in measuring with solids at high frequency experimenters sometimes allow the wave-length to change with the changing dielectric constant of the material in its dispersion range, a considerable practical simplification which complicates the theoretical form of the curve near its apex. When this is not the case, comparison of this value with that obtained in another manner can be used to measure the degree of inhomogeneity.

Where we have measurements at several frequencies we can obtain what is practically  $\frac{d}{dT} \log \tau$  by plotting  $\log$  (frequency) against temperature of maximum loss and measuring the slope of the graph, which should be practically a straight line. When available, this is generally to be preferred to other methods, but entails a large amount of experimental work.

### To Derive $\tau$ .

When a maximum of dielectric loss is observed, the procedure is easy enough.

(1) The imaginary dielectric constant  $\epsilon''$ , the dipole conductivity (proportional to  $\omega\epsilon''$  and to the power loss with constant voltage) and the dipole resistivity (proportional to  $\epsilon''/\omega$  and to the power loss with constant current) all reach their maximum against temperature when  $x = 1$ , *i.e.*, when

$$1 = \frac{\epsilon_1 + 2}{\epsilon_0 + 2} = \frac{\epsilon_1 + 2}{2\pi\nu}.$$

(2)  $\epsilon''/\epsilon' = \tan \delta$ , commonly called the power factor, the phase angle  $\delta$ , and the true power factor  $\sin \delta$ , all reach their maximum when

$$x = \sqrt{\frac{\epsilon_1}{\epsilon_0}},$$

*i.e.*, when 
$$\frac{1}{\tau} = \frac{\epsilon_1 + 2}{\epsilon_0 + 2} \cdot \sqrt{\frac{\epsilon_0}{\epsilon_1}} \cdot \omega.$$

(3) We need not consider here the absorption coefficient specified in the optical manner which is occasionally used in work at very high frequencies and has yet another condition of maximum.

When the measurements do not include a maximum, it is possible to extrapolate from the asymptote provided the magnitude of the loss at maximum is known. This can be calculated from  $(\epsilon_1 - \epsilon_0)$

$$\epsilon''_{\text{max.}} = \frac{1}{2}(\epsilon_1 - \epsilon_0)$$

or from the dipole moment and concentration of a solute in dilute solution. We have on the low frequency, high temperature, side:

$$\tau = \frac{1}{2\omega} \cdot \frac{\epsilon_0 + 2}{\epsilon_1 + 2} \cdot \frac{\epsilon''}{\epsilon''_{\text{max.}}};$$

on the high frequency, low temperature, side:

$$\tau = \frac{2}{\omega} \cdot \frac{\epsilon_0 + 2}{\epsilon_1 + 2} \cdot \frac{\epsilon''_{\text{max.}}}{\epsilon''}.$$

When  $(\epsilon''/\epsilon')$  is used instead of  $\epsilon''$  in these expressions, they must be multiplied by  $\sqrt{\frac{1}{\epsilon_0}}$ .

### To Derive $\tau$ and its Temperature Coefficient from Dielectric Constant Measurements.

$\epsilon'$  reaches its mean value  $\frac{1}{2}(\epsilon_0 + \epsilon_1)$  under the conditions in which  $\epsilon''$  is maximum. At this point of inflection the slope is

$$\frac{d\epsilon'}{dT} = -\frac{\epsilon_1 - \epsilon_0}{2} \frac{d}{dt} \ln \tau,$$

to the same degree of approximation as before. The correction to be added to this when the orientation polarisation varies with temperature according to the Debye theory is

$$-\frac{\epsilon_1 - \epsilon_0}{2T} \frac{(\epsilon_1 + 2)}{(\epsilon_0 + 2)}$$

which is negligible when  $\frac{d}{dt} \ln \tau$  is as large as it is in cases discussed in this paper.

### Analysis of the Reaction Velocity Equation.

Having obtained by one of the above methods a value of  $\tau$  and of  $\frac{d}{dT} \ln \tau$  at a temperature  $T$ , we can evaluate the constants of the Arrhenius equation for reaction velocity

$$\frac{1}{\tau} = k = Ce^{-A/RT}.$$

Thus the  $\alpha$  used in the previous section is identical with  $A/R$ . It is convenient to evaluate  $A/RT$  ( $= -T \frac{d}{dt} \ln \tau$ ) as well as  $A$  and  $C$ . The value found for  $C$  now requires special consideration.

In the simplest case a value between  $10^{13}$  and  $10^{14}$  is expected. A larger value implies activation in many degrees of freedom. Hinshelwood<sup>6</sup> gives an equation which may be brought into the form

$$k = C_1 \frac{e^{-(A/RT + f)} (A/RT + f)^f}{f!}.$$

<sup>6</sup> C. N. Hinshelwood, *Kinetics of Chemical Change in Gaseous Systems*, 1933, p. 128.

Here  $C_1$  is a constant having the normal value  $10^{13} - 10^{14}$  and  $f$  has been written for Hinshelwood's  $\left(\frac{n}{2} - 1\right)$ .  $n$  is the number of quadratic terms in which activation energy is shared, so that  $f$  may be loosely regarded as one less than the total number of vibrations involved in activation. When  $f$  is large we can introduce the asymptotic formula for factorials:

$$f! \approx \left(\frac{f}{e}\right)^f \sqrt{2\pi f},$$

so obtaining

$$k = C_1 e^{-A/RT} \cdot \frac{1}{\sqrt{2\pi f}} \left(\frac{A/RT + f}{f}\right)^f.$$

$C_1$  may be conveniently taken as  $\sqrt{2\pi} \times 10^{13}$  and  $f$  can then be ascertained by trial.

FIG. 2.—Dielectric loss (conductivity) of ice from measurements by Smyth and Hitchcock.

ling" effects) becomes: <sup>4</sup>

$$k' = K \cdot \frac{F_a^*}{F_n} \cdot \frac{kT}{h} \cdot e^{-E_0/kT}.$$

$K$ , the transmission coefficient, is generally taken as 1;  $F_a^*$  is the partition function of the activated state omitting the degree of freedom normal to the potential barrier and calculated using a zero  $E_0$  higher than that used for  $F_n$ , the partition function of the normal state. All degrees of freedom which are the same in both states cancel so that in the simplest

It is to be noticed that if  $f$  varies continuously with temperature, the results will be in error. While  $f$  is increasing,  $A$  and  $f$  will be overestimated; while  $f$  is decreasing they will be underestimated; a stationary value will be estimated correctly.

The transition state treatment of reaction velocities nowadays preferred by some workers leads us to practically the same qualitative picture of the process of reaction. The general reaction equation (omitting "tunnel-

of all cases in which one vibration is converted to a translation by the activation process,

$$\frac{F_a^*}{F_n} = (1 - e^{-h\nu/kT})$$

which approximates to 1 when the frequency of the vibration is high. Our frequency factor  $C$  thus becomes  $kT/h \approx 10^{13}$ . However, quoting from Eyring, as a general phenomenon in reaction rates "with an abnormally high  $E_0$ , there is in general associated an abnormally high  $F_a^*/F_n$ . The reason is that the large  $E_0$  arises from loosening an abnormally large number of bonds (or from loosening very strong bonds), and this automatically means a large value for the ratio  $F_a^*/F_n$ ." The qualitative picture is therefore exactly the same.

### Discussion of Some Experimental Cases.

(1) *Ice*.—The graph (Fig. 2) shows Smyth and Hitchcock's results for ice,<sup>7</sup> logarithmically plotted. This should be compared with the direct

FIG. 3.—Frequency of maximum loss (conductivity) in ice.

graph of  $\epsilon''$  (*loc. cit.*,<sup>7</sup> p. 4642). There are two points of departure from ideal behaviour: the linear portions of the curves on the low-temperature side are not coincident as they should be, and the curves rise above their linear extrapolations at the lowest temperatures. This is especially the case at the highest frequencies. These facts would be explained if there were a small secondary component of loss reaching its maximum at a slightly higher frequency or lower temperature than the range studied. It is true, since these deviations depend on measurements of the lower losses, that they may be due to experimental error; but no single source of error can produce them and the losses should still be quite large enough to measure accurately.

The slopes of eight linear portions of the curves can be measured. They are found to be:

<sup>7</sup> C. P. Smyth and C. S. Hitchcock, *J. Amer. Chem. Soc.*, 1932, **54**, 4631.

Ascending branches	60,	20,	5,	1,	0.5 k.c.
$-\frac{d}{dt} \log_{10} \tau =$	0.38,	0.40,	0.41,	0.41,	0.41
Descending branches	1,	0.5,	0.3 k.c.		
$-\frac{d}{dt} \log_{10} \tau =$	0.40,	0.41,	0.44		
Mean of all,	0.41				
Mean temperature,	250° K.				
Frequency of max. $\epsilon''$ at this temperature = $8.51 \times 10^3$ .					

By plotting  $\log \nu_{\max.}''$  against temperature (Fig. 3), we get another value of  $\frac{d}{dt} \log_{10} \tau = 0.45$ , corresponding to  $T_{\text{mean}} = 253^\circ \text{K.}$ , for which  $\nu_{\max.}'' = 1.17 \times 10^4$ . From these two different results with  $\epsilon_1 = 78$  and  $\epsilon_0 = 3.0$ :

$T_{\text{mean}}$	$-d/dt \ln \tau$	$A/RT$	$A$	$1/\tau$	$C$	$f$
250	0.945	23.6	11,700 cal.	$8.55 \times 10^4$	$1.45 \times 10^{18}$	2
253	1.04	26.2	13,200 cal.	$1.18 \times 10^5$	$2.90 \times 10^{18}$	4 or 5

Of these, the latter is doubtless more accurate.

H. Eyring <sup>4</sup> has already suggested applying reaction velocity theory to this case. Roughly estimating  $1/\tau$  at  $0^\circ \text{C.}$  as 60,000 ( $10^5$  is nearer), and assuming that  $C$  would be normal ( $= hT/h$ ), he estimated the activation energy as about 10,000 cal., which is not grossly wrong though it would not satisfactorily describe the temperature variation. The same method applied to some of the examples below would have given entirely false results.

In the same place Eyring makes a valuable suggestion that the relaxation times of the order  $10^{-12}$  secs. found in normal solvents should be treated in the same way, as reactions with very low activation energies.

(2) **Solid Solutions in Paraffin Wax.**—The experimental information for the butyl stearate solution is very limited, so that the conclusions from it must not be regarded as finally accurate, but they are of the highest importance in comparison with the other paraffin-wax systems (Fig. 4). There is a clear break in the curve between 17 and  $23^\circ$ . In spite of the fact that the measurements refer to rather small losses, it seems quite out of the question that so large a deviation can be attributed to experimental error. Below this temperature the relaxation is a reaction with a normal frequency factor and an activation energy of 6800 calories. Above this temperature we have a reaction with nearly three times the activation energy and consequently a much larger frequency factor, indicating activation in about 60 degrees of freedom. It is a well-known possibility in chemical kinetics, when a reaction can proceed by alternative mechanisms, for the reaction of higher activation energy to supersede the other above a certain temperature at which they have the same velocity. Of course, the frequency factor must be larger, or the reaction of higher activation energy would always be much slower than the other.

[*Note added in proof, 17th October, 1936:* Further work by Mr. Sillars confirms the change of slope shown in Fig. 4 but gives other indications which may demand revision of the interpretation given here. It is however allowed to stand as a convenient introduction to the case of cetyl palmitate.]

The cetyl alcohol case requires no special discussion. The anomalies for power factors less than  $2 \times 10^{-4}$  may fairly be ascribed to experimental error (Fig. 4).

The cetyl palmitate curves require a little care in interpretation (Fig. 5). In the first place, the very steep lines above  $41^\circ$  are considered to be due to a polymorphic transition of the wax, which does not take

place at a single temperature because the wax is not a single substance. The high apparent activation energy of about 60,000 cal. has, therefore, no significance. Jackson, in fact, observed this transition, and was rather

surprised because he supposed it was without effect upon his dielectric loss curves.<sup>9</sup> This demonstrates the superior informativeness of the logarithmic graph. Below this temperature the curves are still clearly unsym-

FIG. 5.—Dielectric loss in 4.78 per cent. solid solution of cetyl palmitate in paraffin wax. Measurements by W. Jackson.<sup>8</sup>

metrical, most probably owing to a change in the temperature coefficient of  $\tau$  in the neighbourhood of  $23^\circ$ , similar to the change at about the same temperature in the butyl stearate case. In this case it is still an abnormally

fast reaction below this temperature, but a very fast one above it.

There is an upper limit to the permissible value of  $f$ , determined by the number of atoms involved in the activation, which cannot be less than about  $f/3$ . In a gas reaction this limit is imposed by the number of atoms in the individual molecule, and the highest value yet found is about 25 in the decomposition of azoisopropane.<sup>10</sup> The value of 140 found for the cetyl palmitate solution above  $23^\circ$  C. cannot well be ascribed to activation by energy concentrated in one molecule, while this becomes impossible in the case of "permitol" described below. However, it

becomes quite possible if we bring in four or more nearest neighbours as well as the central molecule under consideration; while there is no *a priori* objection to spreading the activation much further, so that the only limit is imposed by the number of atoms in the crystal.

It appears that it might be profitable to correlate this experimental evidence of the existence of activation in a very large number of degrees of freedom in these paraffin-wax systems with the theory of co-operative effects in molecular rotation in such crystals.<sup>11, 12, 13</sup> Muller's X-ray crystallographic studies<sup>14</sup> of the higher normal paraffins show that above about 20° C. the crystal shows a gradual change of form, with all the marks of a co-operative phenomenon. The change in, say,  $C_{25}H_{52}$  may be readily interpreted as due to rotational oscillation of the hydrocarbon chains about their axes: this makes the chain behave as if it had more nearly cylindrical symmetry and the crystal structure approach more nearly the hexagonal form: this in turn permits freer rotation and the change builds up rapidly, the *b*-axis ceasing to expand and starting to contract.  $C_{25}H_{52}$  becomes

FIG. 6.—Dielectric loss in chlorinated diphenyl ("Permitol"). Measurements by W. Jackson.<sup>15</sup>

hexagonal at 45° C., and melts at 46° C. In the higher members, the co-operative effect is so strong as to produce an abrupt transition at a certain stage. It is remarkable that these co-operative effects appear at about 20°, which is also the temperature in the neighbourhood of which the rotation of ester molecules in the waxes changes its mechanism to a process governed by activation in many degrees of freedom.

(3) "Permitol."—This synthetic dielectric material, chemically a mixture of isomers of tetrachlorodiphenyl, is of special interest because it is in the physical condition of a glass just above its softening range. It pours slowly at room temperature, and can be cracked and chipped if

<sup>15</sup> W. Jackson, *ibid.*, 1935, **153**, 158.

cooled in ice and salt. Actual viscosity measurements are given in the original paper.<sup>15</sup> Since we have here dielectric-loss measurements covering a very wide range (Fig. 6), the opportunity has been taken to test all the various methods outlined above for deriving  $\frac{d}{dT} \ln \tau$  from experimental data, with the following results (Fig. 7) :

(a) The change with frequency of the temperature of maximum loss gives, as expected, higher values than any other method. These values are taken as the best.

(b) The asymptotes of the descending branches of the logarithmic graph give also quite good and consistent results. Their uniform lowness compared with the results of (a) should be regarded rather as an underestimate by 5° of the mean temperature to which the slopes correspond ; a natural error arising from the regular decrease of slope with rising temperature which makes the curves appear to reach their asymptotes too soon.

(c) The slopes of descending branches at half-height measured on the original graphs are in agreement with (b), but show wider scatter.

(d) All results referring to ascending branches of the curves are low. This might be due to inhomogeneity, in particular to the presence of a small percentage of dipoles of rather higher mobility than the rest, which cannot be unexpected in such a mixture as this.

(e) Values calculated from widths at half-height are intermediate between those of (b) and (c) on the one hand, and (d) on the other, as is to be expected.

The results of (a) only are used in forming the velocity equations. *A* is seen to be rather large throughout the range, rising as temperature falls but appearing to become stationary below 10° C. *C* is also anomalously high throughout the range, varying in sympathy with *A*, and correspondingly *f* approximately doubles in value as

FIG. 7a.—Temperature variation of the temperature coefficient of  $\tau$  in chlorinated diphenyl, variously determined.

(a) —; (b) —⊗—; (c) ⊙; (d) × asymptotes, \* slopes; (e) +; (f) ●, a directly measured temperature coefficient of viscosity.

FIG. 7b.—Temperature variation of frequency of maximum loss in chlorinated diphenyl.

the material is cooled. However, since *f* is varying, these quantities (*A*, *C* and *f*) will all be underestimated above 15° C.; but if, as it appears, *f* is stationary below this temperature, the results in the first three rows should be approximately correct. The rest must only be taken in qualitative significance. Subject to this limitation, they are what may reasonably be expected in a substance on the point of setting to a glass. As temperature falls, the number of bonds which must be loosened, and the increment of energy required to do so, to make a molecule free to turn about, steadily increases.

3.25	307.7	34.6	56.6	.184	$5.25 \times 10^6$	$4.49 \times 10^6$	$1.7 \times 10^{31}$	90

$$\frac{1}{\tau} = 2\pi\nu \left( \frac{\epsilon_1 - 2}{\epsilon_0 + 2} \right) \sqrt{\frac{\epsilon_0}{\epsilon_1}} \quad 2\pi \times 1.36\nu \text{ when } \epsilon_1 = 4.8, \epsilon_0 = 2.8.$$

The close parallelism between  $\tau$  and viscosity in this material is a confirmation of the close connection between the ultimate mechanisms of both, which is obviously seen to be required when any of the theoretical treatments of viscosity mentioned above is examined in comparison with the present treatment of dielectric relaxation. It is to be noticed that the temperature coefficient of  $\tau$  and  $\eta$  in "Permitol" and of  $\tau$  in the paraffin-wax solid solutions is enormously greater than the temperature coefficient of viscosity in most liquids: the temperature coefficient of  $\eta$  for molten paraffin wax is about 0.007 corresponding to an activation energy of 1.6 k. cals.

Kassel<sup>16</sup> has shown that anomalously high apparent activation energies can result when the reaction proceeds through several reversible stages in cascade before the final effective step. This must, therefore, be admitted as alternative to the assumption of activation in many degrees of freedom: but the latter is nevertheless preferred at present as more readily accounted for in the physical nature of the system.

## Summary.

The theory of unimolecular chemical reaction velocities is applied to the process of change of orientation of a polar molecule in a material showing dielectric loss and dispersion. The requisite analysis of experimental data is explained. Experimental results for three different types of physical system are considered:

- (1) Ice,
  - (2) Solid solutions of polar substances in paraffin wax,
  - (3) A polar organic glass at the top of its softening range ("permitol").
- (1), and apparently cases in (2) at low temperature, present fairly normal unimolecular reactions; the rest present very fast reactions, as though activation involved many degrees of freedom. This is thought to be consistent with their physical nature.

Acknowledgment is due to the Department of Scientific and Industrial Research for a grant, to the author's laboratory collaborators for experimental figures placed at his disposal, and to Mr. C. N. Hinshelwood for a discussion.

# ON THE MOVING BOUNDARY METHOD OF MEASURING CATAPHORESIS.

BY J. J. BIKERMAN.

*Received 1st October, 1936.*

The observed velocity of the moving boundary between a sol and a supernatant liquid depends on the nature of this liquid. Attempts to eliminate its influence or find out which supernatant liquid gives the correct value, *i.e.*, the mobility of the sol particles within the sol, have not given a satisfactory result.<sup>1</sup>

If, however, we use as supernatant liquid for a given sol another sol which is practically identical with it but of a different colour (or refractive index), the rate of movement will obviously correspond closely with the particle mobility within the homogeneous sol.\* We know, for instance, that gold sol particles covered with gelatin move with the same velocity as gelatin particles alone;<sup>2</sup> observation of the boundary between a pure gelatin solution and a solution of gelatin infected with gold would, therefore, give the correct mobility.†

One would not expect, however, that the boundary between two gelatin solutions would move at a rate appreciably different from that of the boundary between a gelatin-in-buffer-solution and the unmixed buffer solution, because small amounts of gelatin change the electrical conductivity and other relevant properties of the relatively concentrated buffer solution hardly appreciably. The largest differences between the mobilities measured in the old and in the new way should occur when very many highly charged particles are suspended in a solution containing but few ions. An arsenic trisulphide sol would be a perfect example of such a sol if the common formation equation  $\text{As}_2\text{O}_3 + 3\text{H}_2\text{S} = \text{As}_2\text{S}_3 + 3\text{H}_2\text{O}$  were complete, but, even after taking in account the forming of oxidation products of  $\text{H}_2\text{S}$  and so on,  $\text{As}_2\text{S}_3$  seemed to be suitable. As indicator  $\text{HgS}$  was used.

I observed, accordingly, the moving boundary between a mixed  $\text{As}_2\text{S}_3$ — $\text{HgS}$  sol and an  $\text{As}_2\text{S}_3$  sol. The constant sharpness of the boundary and the concordant mobilities of direct and reverse movements showed the practicability of the method. To prove that the visible mobility was identical with the mobility of  $\text{As}_2\text{S}_3$  particles the transport of the sol was measured in the same apparatus both by the Hittorf and by the

† Such experiments (with gelatin-kieselguhr against gelatin) were published by A. L. Roberts and J. C. Carruthers, *J. Physic Chem.*, 1936, **40**, 703, just before my work was accomplished.

moving boundary method; the results were consistent. We may, therefore, conclude that the boundary moves at the same rate as  $\text{As}_2\text{S}_3$  particles in an almost homogeneous sol.

The new method is obviously inapplicable when the mobility of an old sol is to be determined. This mobility, however, will generally be a purely fortuitous magnitude. If reliable figures for the mobility of a sol are required in order to compare them with other properties of the sol, the "supernatant liquid" may be prepared together with the sol and the new method may be applied.

### Apparatus.

The apparatus chiefly used in present experiments was a modification of the "sheared boundary" apparatus of MacInnes.<sup>3</sup> As in MacInnes' pattern, the resistance glass tubes A and B were fitted into the discs *a* and *b*. The disc *a* could be turned so as to make A a prolongation of B and to form a boundary in their separation surface. The section of the tubes was 0.202 cm.<sup>2</sup>. A new kind of electrode vessel had to be adopted since colloid solutions are more sensitive to traces of electrolytes (electrolysis products or salts of an unpolarisable electrode) than ionic solutions. When, for instance, a  $\text{Zn}/\text{ZnCl}_2$  electrode was used, much  $\text{As}_2\text{S}_3$  coagulated in contact with  $\text{ZnCl}_2$  solution and the resulting streaming of the liquid carried some zinc ions outside the electrode cell.\*

Satisfactory results were obtained with electrode vessels shown in Fig. 1. C is a copper wire in a copper chloride solution, G is a 3.5 per cent. gelatin gel containing 0.001 N  $\text{NH}_4\text{Cl}$ , the tubes T (0.38 cm. diameter) and U prevented the mixing of the electrolysis products with the sols in A and B. The filling of A and B was facilitated by using rubber stoppers and the taps *t*. As no special suspension of the apparatus<sup>4</sup> was employed the boundary was only sharp when the density difference between both layers was considerable.

The "sheared boundary" arrangement presents two inconveniences: the impossibility of observing the boundary from the first moment of its formation and the difficulty of keeping clean the lubricated ends of the tubes and the holes in the discs. The method possesses, however, two important advantages: (a) the boundary is formed with but small

FIG. 1.—(U is intended to refer to the small tube inside the electrode cell.)

<sup>3</sup> D. A. MacInnes and L. G. Longworth, *Chem. Reviews*, 1932, 11, 171.

\* With such electrodes I sometimes observed the uprising of the lower liquid in a "chimney shaped" regions as described by MacInnes, Cowperthwaite and Huang, *J. Amer. Chem. Soc.*, 1927, 49, 1710. MacInnes explained the phenomenon as due to a preferential warming by the current of the lower solution, which in his experiments was of lower conductivity. The explanation is not applicable to my observations, as the "chimneys" appeared only when the boundary rose and did not appear at reversal of the current although the asymmetrical heating does not depend on the current direction.

<sup>4</sup> D. A. MacInnes, I. A. Cowperthwaite and T. C. Huang, *J. Amer. Chem. Soc.*, 1927, 49, 1710.

disturbance, (b) if it is not sharp enough we can let out a drop each from tubes A and B and establish a new boundary without rejecting the whole solutions.

In the transference experiments the tubes T were composed of two pieces ground together; the outer piece contained copper solution and gelatin gel, the inner piece was filled with the "supernatant" sol. After the experiment both pieces were separated and the contents of the inner piece added to the sol in A. The sol, then, was precipitated with HCl and  $\text{As}_2\text{S}_3$  weighed. The most important error in the analysis originates in the difficulty of removing the  $\text{As}_2\text{S}_3$  precipitate from the gelatin surface without picking up some gelatin.

### Solutions.

The connection between the HgS and the  $\text{As}_2\text{S}_3$  in the lower sol had to be made as intimate as possible; the conductivity of the mixed sol had to be nearly equal to the conductivity of the upper sol.

A saturated solution of yellow HgO in boiling water\* was cooled and precipitated with hydrogen sulphide. To this sol a solution of  $\text{As}_2\text{O}_3$  was added and  $\text{H}_2\text{S}$  conducted through the mixture; it was expected that HgS particles would function as nuclei for  $\text{As}_2\text{S}_3$ . A part of the HgS formed, however, distinct grains which sedimented within some days or weeks. The remainder was stable but partly consisting of larger particles than the  $\text{As}_2\text{S}_3$  sol.

By adding an arsenic trioxide solution to water which had been boiled for the same time as the HgO solution in an identical flask and saturated with  $\text{H}_2\text{S}$ , and treating the sol thus formed in exactly the same manner as the HgS- $\text{As}_2\text{S}_3$  mixture, we get sols whose conductivity sometimes coincides with the conductivity of the mixture, but may differ, too, by some 30 per cent. If a "subnatant liquid" for a given  $\text{As}_2\text{S}_3$  sol is required, there is no difficulty, however, in obtaining it by mixing together two preparations of the mixture HgS- $\text{As}_2\text{S}_3$  made at the same time as the preparation of the  $\text{As}_2\text{S}_3$  sol, or by mixing a HgS- $\text{As}_2\text{S}_3$  sol with the  $\text{As}_2\text{S}_3$  sol. Since the conductivity of  $\text{As}_2\text{S}_3$  solutions is not constant the subnatant liquid is adjusted shortly before the experiment.

In the experiments 4, 5, and 6 of Table I. the conductivities were equalized by adding slightly different amounts of  $\text{NH}_4\text{Cl}$  in an extreme case 0.00105 mol./l.  $\text{NH}_4\text{Cl}$  to the lower sol and 0.00100 mol./l. to the upper sol. It is generally known that such differences do not affect the mobility appreciably.

The arsenic trisulphide sols contained more than 8 gms.  $\text{As}_2\text{S}_3$  per liter, while the concentration of HgS was less than 0.2 gms. per liter. The difference between the densities of the two layers would, therefore, be too small if the  $\text{As}_2\text{S}_3$  concentration were exactly the same. The lower solutions were, accordingly, prepared with a surplus of about 5 per cent.  $\text{As}_2\text{S}_3$ , or with the addition of some sugar. The mobility of colloid particles is not affected by such small differences in the sol concentration. That even 1.5 per cent. sugar does not change the boundary movement has been proved by experiment.

### Measurements.

The potential gradient employed was between 1 and 2 volts per cm.

The temperature in Section I. was  $18.2^\circ$ - $19.1^\circ$  and, in Section II.,  $17.2^\circ$ - $19.7^\circ$ .

In the measurements of Section II. both rising and falling boundaries were observed; in Section I. only rising ones. The readings were made with the naked eye.

\* The solubility is (according to K. Schick, *Z. physik. Chem.*, 1902, 42, 172) 0.41 gm./l. Two of my solutions contained 0.42 and 0.38 gm./l.

The mobility in unit field was calculated by the equation

$$u = \frac{lq\kappa}{it}$$

where  $l$  is the displacement of the boundary in  $t$  sec.,  $i$  the current strength,  $q$  the section of the tube A, and  $\kappa$  the conductivity of the sols. Of these quantities,  $t$ ,  $q$  and  $i$  can be measured with a far higher precision than  $l$  and  $\kappa$ . The gross displacement  $l$  was from 2 to 3 cm.; as the error of reading cannot be reduced to less than 0.04 cm. the relative error of  $l$  is at least 1 to 2 per cent. The relative error of  $\kappa$  is even larger when sols without added salt are investigated. To prove that the solutions remain unchanged during an experiment I determined their conductivity in a small conductivity cell both before and after the cataphoresis.

After the cataphoresis the contents of tubes A and B, excluding those of U and T, were used. In sols with about 0.01 N  $\text{NH}_4\text{Cl}$  the difference did not exceed 0.5 per cent.; with pure sols, however, the recovered fractions conducted considerably better than the original preparations. When the difference exceeded 5 per cent. the results were rejected. I did not attempt to reach a higher precision as my task was to improve, not the precision of the moving boundary method, but its reliability.

TABLE II.

$\text{NH}_4\text{Cl}$ mol $1 \times 10^{-3}$	$\kappa$ $\text{ohm}^{-1} \text{cm}^{-1} \times 10^{-4}$	$u^A$ cm. sec. $10^{-4}$ per volt cm	$u^B$ cm. sec. $10^{-4}$ per volt cm

## Results.

*Section I.*—In Table I. the analytically measured transport ( $T_a$ ) is compared with that calculated from the boundary displacement ( $T_b$ ). The sols contained about 0.001 mol./l.  $\text{NH}_4\text{Cl}$ , the concentration of the  $\text{As}_2\text{S}_3$  sol was 7.96–8.32 gm./l., of the  $\text{HgS}-\text{As}_2\text{S}_3$  mixture 8.60–9.20 gm./l.  $u$  is the velocity of the rising boundary in a unit field.

*Section II.*—I compared, at different  $\text{NH}_4\text{Cl}$  concentrations, the movement of the boundaries  $\text{As}_2\text{S}_3 + \text{NH}_4\text{Cl}$  aq. against  $\text{HCl} + \text{NH}_4\text{Cl}$  aq. and  $\text{HgS} + \text{As}_2\text{S}_3 + \text{NH}_4\text{Cl}$  aq. against  $\text{HCl} + \text{NH}_4\text{Cl}$  aq. (Table II.). The concentration of  $\text{NH}_4\text{Cl}$  in the sols and in the supernatant liquid was the same, while to the supernatant liquid as much  $\text{HCl}$  was added as was

required to make its conductivity equal to the conductivity of the sol  $+ \text{NH}_4\text{Cl}$ . The rising boundary was mostly sharp, the falling boundary (its velocity being denoted by  $u \downarrow$ ) diffuse, especially in the experiments without, or with only a little,  $\text{NH}_4\text{Cl}$ ; the figures for  $u \downarrow$  reported in the tables refer to the "boundary" between the clear supernatant liquid and the transition layer; the "boundary" between the transition layer and the apparently unchanged sol usually moved faster.

Table II. (3) contains results obtained by the new method. The superiority of the "two sols boundary" is obvious. The figures for  $u \uparrow$  and  $u \downarrow$  are more consistent than in (1) and (2) so long as the  $\text{NH}_4\text{Cl}$  content is small. With much  $\text{NH}_4\text{Cl}$  the conductivity of the sol particles plays but a subordinate rôle and the difference between  $u \uparrow$  and  $u \downarrow$  becomes accidental and small in all cases.

Henry and Brittain<sup>1</sup> derived from the Kohlrausch-Weber theory that  $u \uparrow > u \downarrow$  and  $u \downarrow > u$ , when  $u$  denotes the true mobility, and both  $u \uparrow$  and  $u \downarrow$  are determined with an ionic supernatant liquid the ions of which liquid move faster than the colloid particles. This conclusion, made for true mobilities, holds for most of the mobilities of Table II. (3).

### Summary.

Experimental investigations have been made of an improved method of measuring cataphoresis based on the observing the movement of a boundary between two almost identical sols of different colours.

I am indebted to Mr. D. C. Henry for hospitality and help and to the Professional Committee for German Jewish Refugees for a maintenance grant.

University of Manchester.*

### REVIEWS OF BOOKS.

**Atomtheorie.** By A. HAAS. Berlin: Walter de Gruyter & Co. Pp. viii and 292. Price R.M. 8.50 and R.M. 10.

This work is too well known to need detailed description. In this, the third, and very much enlarged edition, the author makes a gallant effort to keep his readers informed of the latest developments in the breathless story of atomic physics. The seven sections of the book deal with, *Elektronen, Atome und Lichtquanten; die Grundlagen der Atommechanik; die Spektren der Atome; die Röntgenstrahlen; die Atomkerne; die Molekeln; die Wechselwirkung zwischen Licht u. Materie.*

The treatment is throughout strictly elementary, and marked with those qualities of precision, clarity and distinction which are associated with the name of the author.

It may be remembered that a generation ago, an effort was made to present the Spencerian philosophy in compressed form by applying a footnote to Spencer's voluminous pages, and compressing the contents of each page to one-tenth of its original value.

Professor Haas's book is presented in seven chapters and sixty-six subsections. Not the least interesting feature of the book is an appendix of some sixteen pages, in which, in sixty-six paragraphs, corresponding

paragraph by paragraph with the sections of the full text, is given a complete and most helpful conspectus of the contents of the volume. Although this may be putting a premium on idleness, as doing for the student what he ought to do for himself, there is no denying the usefulness of such an appendix.

The simplicity and clarity of the exposition are a measure of the care and thought which has gone to the writing of a volume which may be unreservedly recommended to the university student.

A. F.

**Annual Reports on the Progress of Chemistry**, Vol. XXXII FOR 1935.  
(London : The Chemical Society. Pp. xiii and 527. Price 7s. 6d. net.)

The amount of material reported this year which bears directly on work with which the Faraday Society is concerned is greater than ever. Special mention may be made of the following reports : Radioactivity and sub-atomic phenomena (H. J. J. Braddick), Isotopes (S. Glasstone), Spectroscopy (G. B. B. M. Sutherland), Determination of thermodynamic constants (Glasstone), Chemical Kinetics (E.A. Moelwyn-Hughes), Surface chemistry (E. B. Maxted), Physical basis of optical rotatory power (G. B. Allsop), Dipole moment, and valency angles (Glasstone), Non-ferrous alloy systems (E. S. Hedges), Crystal physics and crystal chemistry (J. D. Bernal), Properties of real crystals (Bernal), Molecular crystals (D. M. Crowfoot), Polymerisation (E. H. Farmer).

These reports, however, by no means exhaust the interest of the physical chemist. Moreover, the volume provides the usual admirable survey of work in those allied branches of the science into which the influence of the physical chemist and of the chemical physicist is more and more penetrating.

**Die Umwandlungen der chemischen Elemente.** By ARTHUR HAAS  
(Walter de Gruyter and Co. 118 pages and 31 figures.

This little book gives a vivid account of recent work on the new subject of nuclear physics and chemistry. It commences with a survey of the properties of radiation and of stable atomic species which is followed by a discussion of the methods used to disintegrate nuclei. The results of disintegration experiments are then considered and a final chapter is devoted to artificial radioactivity.

The subject is treated descriptively and without mathematics but numerous diagrams and photographs add greatly to the value of the book. No less than nineteen photographs of cloud chamber tracks are provided and give striking demonstrations of such phenomena as the production of positrons, the disintegration of lithium by protons and deuterons and many other atomic disruptions.

S. S.

**Allgemeine Photochemie.** By J. PLOTNIKOW. Second Edition, revised and enlarged. 909 pp., with 218 Figures. (Walter de Gruyter & Co., Berlin and Leipzig, 1936. Price RM 28.50 ; bound RM 30.)

This edition bears practically no relation to the first (1910) although it contains a description of most of the early work in Photochemistry. The author has described a large amount of work other than his own, but

has included very few of the modern theories. The book is most comprehensive, particularly in the field of applied photochemistry, and contains a large number of references not given in other text-books on this subject; several of these were found, however, to be incorrectly given. The author concludes his book by a list of his 215 contributions to the scientific literature.

C. F. G.

**Kolloidik.** By A. VON BUZAGH. (Dresden, Theodor Steinkopff. Pp. xii + 323. Price RM. 15.)

The subtitle of this work describes it as "An Introduction to the Problems of Modern Colloid Science," while the title itself is stated to be a term coined by Professor Spiro to cover both colloid chemistry and colloid physics. The conservative reader will probably consider it unnecessary and will have the same feeling about a good deal of the exuberant nomenclature applied to a number of stereometric objects and relations.

They occur in the first chapters, devoted to the definition and classification of disperse and "difform" systems, the fundamental characteristic of which is periodic discontinuities in one or more properties. After discussing them, the author proceeds to give what he calls "the most general definition of the colloidal state" as follows: "Colloidal discontinuities are such spatial discontinuous alterations of properties as are coupled with continuities of the order of magnitude between the wave-length of light ( $500\text{ m}\mu$ ) and the average molecular size ( $1\text{ m}\mu$ ). Systems with this structure are described as colloidal systems. Modern "kolloidik" is the science—the physics and chemistry—of 'colloidal discontinuities.'" He supports this definition by showing that a number of "dispersity functions," *i.e.* formulæ for certain properties containing the particle radii as independent variable, pass through maxima or minima, or show a greatly increased rate of change, when the radius falls within the colloidal range. Whether the validity of general laws in the colloidal range is really a reason for what the author calls "The autonomous way of regarding colloids" seems doubtful on etymological grounds, apart from other objections to these political metaphors. In trying to prove here and elsewhere that colloid science is to be considered a separate discipline the author is flogging a dead horse; the enormous bulk of material makes such a course inevitable for practical reasons.

What has been said above covers the contents of the first four chapters. The fifth, entitled "The morphology of disperse and difform systems" is for the greater part still concerned with the formulation and classification of largely ideal configurations. The contents of the remaining chapters are: VI, Aggregates (Primary); VII, Aggregates (Secondary); VIII, Phenomena at Interfaces (Adsorption); IX, Phenomena at Interfaces (Electrical Properties of disperse systems); X, Changes of State of Colloids (Genesis of colloidal solutions); XI, Changes of State (The Destruction of Colloidal Solutions); XII, (Internal Changes of State in Colloids).

The last five chapters, which contain substantially what the reader expects to find in a text-book of colloid science, cover 120 pages, or somewhat less than half the text. The author throughout insists on the difference between physical boundary zones and geometrical interfaces, which

leads him to reject the "chemical" theories of adsorption and of the electric charge on particles. Such criticisms are always expressed with fairness and urbanity. Perhaps the author's avowed intention to write something more than a text-book accounts for the disproportion between the space devoted to this section and that of 77 pages covered by the two chapters on "Aggregates," which attempt to give a general survey of the structure of matter.

It is this tendency, apparent throughout the work, of beginning very much at the beginning, which makes one feel somewhat uncertain as to the class of readers for whom the book is intended. It is hardly suitable for those approaching the subject for the first time, but will be of interest to those possessing a reasonable knowledge of it as the first complete and consistent statement of the views of the Leipzig school of colloid science. Since this is at present the only school left in Germany, this interest may well become an historical one in the future.

E. H.

**Physical Aspects of Organic Chemistry.** By W. A. WATERS, M.A., Ph.D. George Routledge and Sons, Ltd. Pp. xv + 501. 25s. net.

This valuable book deals with the developments in organic chemistry which have arisen from modern theories of valency and electronic theories of organic reactions. The main theme is the existence of two types of chemical bond, polar and non-polar, and the classification of reactions into two corresponding groups which involve ions and free radicals respectively. A wide range of chemical theories is surveyed, usually from the historical standpoint and the treatment is vivid and interesting. The chapters on hydrolysis, on molecular rearrangements, and on aromatic reactions are particularly valuable and give a well-arranged and fully documented introduction to modern work on these subjects.

The book was originally planned in collaboration with Professor T. M. Lowry who contributes an introduction. The views of the Cambridge School naturally receive special attention but are not unduly emphasised, and the author is to be congratulated on a well-balanced account of modern theories of organic chemistry.

S. S.

**A Text-book of Organic Chemistry (Schmidt).** Third English Edition. By H. GORDON RULE. London: Gurney & Jackson, 1936. Pp. xxiv and 865. Price 25s. net.

The previous editions were reviewed in these *Transactions* (22, 108, and 28, 662). There has been no intervening German edition, so that the judicious and critical additions (and no less careful deletions to ensure, nevertheless, an increase of only 22 pages in size) are due entirely to Dr. Rule. The text has been carefully revised and the constant references to work between 1932 and 1935 provide sufficient evidence that here is a text-book which definitely does not warrant the oft-heard criticism that new work does not find its way into text-books for at least ten years.

It is perhaps from the introductory 98 pages that the physical chemist will judge the volume; recent work, for instance, on stereochemistry and dipole moments is adequately summarised. Later sections deal with other

matters which have recently exercised this Society, *e.g.*, the molecular structure of starch and the constitution of cellulose. There is a new section devoted to vitamins and hormones.

The production is excellent; the judicious use of clarendon type in the text, in particular, enables speedy reference from index to text.

**The Thermochemistry of the Chemical Substances.** F. R. BICHOWSKY and F. D. ROSSINI. (Reinhold Publishing Corp. N.Y., 1936. 35s.) (Chapman and Hall, Ltd., London.)

This book contains self-consistent "best values" of the heats of formation of all chemical substances which have been measured, except organic compounds having more than two carbon atoms. The list includes heat values from spectroscopic data for excited states and unstable molecules, but no values for deuterium compounds appear. It is a recalculation and extension of the data presented in the International Critical Tables, and as a book of reference is a necessity for a scientific library. The authors have arranged the tables in a very precise and simple form, and in a separate section give a brief critical survey of the experimental work relating to each substance. It is no fault of the book, but a reflection on the trend of experimental science, that a vast number of the results are derived from the work of Thomsen and Berthelot now fifty or so years old. To quote the preface: "The authors have been reluctant not to use the almost universally accepted standard temperature of 25° C. for thermodynamic calculations; but the selection of 18° as the standard temperature is practically necessary in this case because all of the monumental work of Julius Thomsen and of Marcellin Berthelot was done at or near 18°, and there are not now available sufficient heat capacity data with which to make accurate conversion to 25°." The following typical notes on the data of some common substances are significant: "HCN (g). The data on the heat of combustion are: Thomsen (before 1886) 158.5; Berthelot (1881) 159.3. CS<sub>2</sub>. Thomsen (before 1886) measured the heat of combustion of gaseous carbon disulphide, and Berthelot (1881, 1893) that of the liquid." The references to work on formic acid are dated 1852 and 1886 for the vapour, and 1873 to 1892 for the liquid. About fifteen years ago the subject of accurate calorimetry was taken up by a number of contributors to the Journal of the American Chemical Society, but the elaborate machines constructed were not used for any extensive revision of the older results, except for the work now being carried out by Rossini on organic compounds.

E. J. B.

THOMAS MARTIN LOWRY

# THOMAS MARTIN LOWRY, C.B.E., F.R.S.

(1874 to 1936).

THE FARADAY SOCIETY mourns the loss of Professor T. Martin Lowry, one of its distinguished Past-Presidents.

This memoir speaks only of his work for the Faraday Society. He watched and guided its progress with a keen personal pride and thus helped to contribute much to the sum of human knowledge. This work we gratefully record; others may speak of the work of his laboratory which is to be found not only in the pages of these *Transactions* but in many other journals.

Dr. T. Martin Lowry was a founder-member of the Society and from its very early days took an active interest in the organisation of its activities. The Society's early records show that he was an auditor in 1905 and became a member of Council in 1906. This Council, on the 27th November, 1906, decided that steps should be taken to bring into the new Society more of those who were engaged in pure physical chemistry. As one means to this end the Earl of Berkeley was invited to show his experiments on Osmotic Pressure. From this simple invitation there arose a meeting, held on 29th January, 1907, at which papers were read not only by Berkeley but also by Lowry, Dampier-Whetham and Kahlenberg (of Wisconsin). The papers and the discussion were reported together, under the title of a "General Discussion on Osmotic Pressure." In May, 1907, the success of this meeting warranted the organisation of another "General Discussion" on the subject of "Hydration," which was organised by Lowry and the secretary (F. S. Spiers), and took place in June, 1907.

Thus Lowry laid the foundations of a policy on which the success of this Society has largely been based; he realised the value of specialised discussion of a topic limited in scope but of general interest and, nearly 30 years ago, appreciated the importance of inviting distinguished overseas workers to co-operate. The reputation of these "General Discussions," organised along the lines laid down in early 1907, grew to such an extent that when, after almost continuous service to the Society in one capacity or another, Lowry was, in 1928, elected President, he had the privilege of welcoming many distinguished workers who had travelled the seven seas to meet together under his Presidency.

Members of this Society will long remember him, not only for his part in the growth of the Society, but also as their host on the many occasions when, as Professor of Physical Chemistry, he welcomed the Society to Cambridge. It was fitting that Lowry should have been President during the 25th Jubilee year of the Society and that the (50th) "General Discussion," that on Free Radicals, should have been held in his laboratory.

# DIAMAGNETIC SUSCEPTIBILITY OF THALLIUM COMPOUNDS.

BY VIOLET CORONA GWYNNE TREW.

*Received 20th July, 1936.*

## Part I. Thallous Compounds

A study of the literature dealing with the magnetic properties of the chemical elements reveals that very little systematic study has been made of a wide range of compounds of one chemical element. The work of Ikenmeyer<sup>1</sup> on the magnetic susceptibilities of the alkali metal halides only covers one type of compound. Sugden,<sup>2</sup> in 1934, investigated a range of silver and copper compounds, and Spencer and Hollens<sup>3</sup> the compounds of cadmium, but these represent practically the only systematic investigations in this field.

In the present paper the diamagnetic susceptibilities of some thirty thallous salts have been measured, covering a wide range of compounds. From the molar susceptibilities of the salts, the gram ionic susceptibility of the thallous ion has been calculated, and the value compared with the theoretical one obtained from Slater's approximate wave functions. Values of the average mean square radius, and the radius of the outer orbit of the thallous ion have been deduced from the experimental data and are compared with the corresponding values from theory.

## Experimental.

### Preparation of Compounds.

A good commercial specimen of thallous carbonate (99.95 per cent. pure) was used as starting material and was tested for ferromagnetic impurities, *e.g.*, iron, nickel, and cobalt, by B.D.H. spot tests and gave negative or negligible results. Lead was also tested for and found absent. The compounds measured were prepared and purified by the usual methods from A.R. materials. All acids used were tested and shown to be free from iron. In a few cases special methods were necessary to obtain a pure specimen. Thallous bromate prepared by addition of bromic acid to thallous carbonate resulted in an impure product, which even after recrystallisation contained an appreciable amount of thallic bromate as impurity. A pure specimen was obtained by addition of A.R. potassium bromate to pure recrystallised thallous nitrate, thallous bromate being precipitated. A pure specimen of the sulphite could not be prepared by double decomposition of thallous sulphate and sodium sulphite, but was obtained from a solution of the hydroxide, which was first saturated with sulphur dioxide to form the bisulphite. By addition of an equivalent amount of thallous hydroxide solution to this, crystals of the normal sulphite were obtained, on careful evaporation. Attempts to prepare

<sup>1</sup> Ikenmeyer, *Ann. Physik*, 1929, 169.

<sup>2</sup> Sugden, *J.C.S.*, 1932, 161.

<sup>3</sup> Spencer and Hollens, *J.C.S.*, 1935, 495.

the permanganate by Meyer's method<sup>4</sup> proved unsuccessful, oxidation of the thallous compound to thallic oxide resulting in every case, even at low temperatures.

### Analysis.

The purity of the compounds prepared was determined by the tests for ferromagnetic impurities, and by estimation of the thallium content of the compound. Thallium was estimated as chromate, the method being previously tested with a pure recrystallised specimen of thallous sulphate and was found to give consistent results with an error of less than 0.1 per cent. under the following conditions: To 0.3-0.4 gm. of the thallium salt, dissolved in 200 c.c. of water, and made alkaline with a few drops of ammonia, 2 gms. of solid A.R. potassium chromate were added at the boiling-point. The precipitate was stirred until complete coagulation resulted, cooled, allowed to stand for 12 hours, and filtered cold through a sintered glass crucible. The precipitate was washed with 50 c.c. of 1 per cent. potassium chromate solution, and 100-150 c.c. of 50 per cent. alcohol, which was found to be the amount necessary in most cases to wash free from other ions. The precipitate was then dried at 120° and weighed.

It was found necessary to keep strictly to the above conditions as variable results were obtained with more dilute or concentrated solutions, or on washing with water alone. Any compound giving a thallium content differing by more than 0.2 per cent. from the theoretical value was recrystallised.

### Measurement of Susceptibility.

The mass susceptibility was measured by a modified Gouy method as previously described,<sup>6</sup> at atmospheric temperature. Six closely agreeing measurements, each the mean of three readings, were made on the solid salt with fresh packings of substance in each case. The maximum deviation from the mean value was never greater than 2 per cent. and in most cases of the order 1 per cent.

### Results.

In Table I. results are tabulated in three groups, in order of increasing number of electrons  $N$ , the first consisting of salts of thallium with univalent negative ions, the second with divalent and trivalent ions; and the third of organic salts. The mean experimental magnetic mass susceptibility  $\chi$  is recorded in column 3, for each compound, and the molar susceptibility,  $\chi_M = \chi \times M$  in column 4. Column 5 gives values of  $\delta$  representing the ionic susceptibility of the negative ion which must be subtracted from the molar susceptibility to give the ionic susceptibility of the thallous ion. This method of determining the ionic susceptibility assumes that the salts are polar, and that the molar susceptibility is made up of the sum of the ionic susceptibilities. The values of  $\delta$  in the first two groups are taken from the International Critical Tables VI., p. 349, except those marked (a) which are due to Sugden,<sup>2</sup> and (b) which were specially determined, as described below, no values being given in the literature. In these latter cases the susceptibility of the corresponding potassium salt was measured and the value for the negative ion calculated from the known value for the potassium ion. The experimental results so obtained are shown in Table II. The values of  $\delta$  for the organic salts were obtained from Pascal's values for atoms and linkages. In addition, the value for the nitrite ion was obtained by calculation from the

nitrate ion, the chromate similarly from the dichromate, and the carbonate by the same method as the organic salts. Column 6, Table I., shows  $\chi_A$  the resulting atomic susceptibility of the thallous ion.

### Discussion of Results.

The molar diamagnetic susceptibility of a polar salt in the solid state may, in general, be regarded as the sum of the susceptibilities of the positive and negative ions. For a mononuclear spherically symmetrical atom or ion this is given by Langevin's equation:—

$$\chi_A = -\frac{e^2 L}{6mc^2} \Sigma \bar{r}^2 = -2.83 \times 10^{10} \Sigma \bar{r}^2$$

where  $\Sigma \bar{r}^2$  on the classical theory is the mean square radius summed for all the electrons in the atom or ion, or on the newer quantum mechanical view is the square of the average effective electron density distribution.

In solid crystals the interionic distances depend on the ionic radii and hence the factors which determine such distances in a crystal must to a large extent influence the susceptibility. The ionic radius, or outer electron density distribution of an ion is limited in a crystal by adjacent ions, so that the radii of such ions, together with the diamagnetic susceptibility (to which the outer shell of electrons contributes by far the largest amount), should be less than that of the free ion, or the ion in solution.

\* This value is taken from unpublished work by G. T. Oddie (Sister Mary Cecilia) working in this Laboratory.

Furthermore, Goldschmidt <sup>6</sup> has shown that the ionic radius is modified by the co-ordination number of the ion (*i.e.*, the number of ions of opposite sign surrounding the ion in question) as also by the nature and size of such ions. The interionic distance has been shown to decrease with a diminution of the co-ordination number by an amount of the order 3.8 per cent. Similar variations in atomic diamagnetic susceptibility would be expected to follow. In particular, since the number of ions of opposite sign (and hence the co-ordination number), surrounding a given ion is less in its salts with divalent ions than with univalent ions, the diamagnetic susceptibility might be expected to be lower in the former case. The results in Table I. show that for the thallous ion the mean ionic susceptibility as determined from the salts with divalent and trivalent anions is  $-37.4 \times 10^{-6}$ , while the value from the salts with univalent anions is  $-38.4 \times 10^{-6}$ , in exact accord with Goldschmidt's observations on change of ionic radius with co-ordination number. Allowing for the fact that the salts investigated are not all of the same type, it is striking that this decrease is of the same order (about 3 per cent.) as that found by Goldschmidt.

In the case of the organic salts, it will be noted that while the simple salts give a value for the atomic susceptibility of the thallous ion in agreement with that derived from the salts with univalent anions, the salts with larger organic molecules give a very much higher value. This becomes very evident if these salts are rearranged in order of increasing number of carbon atoms in the molecule, when it will be seen that, roughly, the value of the ionic susceptibility increases with the number of carbon atoms. It should be noted that this increase is not due to any bond effects within the anion, as these have been included in calculating  $\delta$  for the organic anion by Pascal's method. It appears, therefore, that the increase in size of the negative ions surrounding the thallous ion results in an increase in the effective ionic radius and hence of the susceptibility of that ion. The organic anion thus appears to have a "diluting" effect on the charge surrounding the thallous ion, and so raises its ionic susceptibility to a value nearer to that of a free ion.

<sup>6</sup> Goldschmidt, *Trans. Faraday Soc.*, 1929, 253.

The results in Table I. have been arranged in order of increasing number of electrons within the molecule and it will be seen that there is, on the whole, a linear increase of molar susceptibility with increasing number of electrons, although certain very marked deviations do occur. In particular, the values for the chloride, thiocyanate and iodide are considerably higher than the average. Salts with anions of similar constitution, *e.g.*, nitrate, chlorate, bromate, and iodate, form a definite linear sequence. Ikenmeyer,<sup>1</sup> has shown that an approximately linear relationship holds for the gram molar susceptibilities of the alkali halides, determined from measurements in solution, when the susceptibilities are plotted against number of electrons in the molecule. The susceptibility can be expressed in the form  $\chi_M = c_1 N_m + c_2$  where  $N_m$  is the sum of the atomic numbers of the atoms in the molecule, or total number of electrons,  $c_1$  is a general constant  $= 0.803 \times 10^{-6}$  and  $c_2$  a constant specific for a given series of salts. The molar susceptibilities of the thallous compounds in general agree with the same relationship, allowing for the much wider difference in types of compounds considered. For thallous salts,  $c_1$ , the average increase in diamagnetism per electron is approximately  $0.7 \times 10^{-6}$  (agreeing reasonably well with Ikenmeyer's value) while  $c_2$  has an average value of  $-17 \times 10^{-6}$  becoming lower by about five units for the chloride, acetate, thiocyanate and iodide, and similarly higher for the nitrate series of ions. The relation holds for the divalent and univalent anions if one-half and one-third of  $N$  and  $\chi_M$  are used respectively. The citrate, benzoate and tartrate are again exceptional. These and the other deviations from linearity are probably due to the cause already discussed, namely, specific effects due to the crystalline form of the compounds investigated.

### Comparison of Theoretical and Experimental Susceptibilities.

The values of  $\Sigma f^2$  in the Langevin formula have been evaluated for the different electron groups in atoms and ions, by Pauling<sup>7</sup> from quantum mechanics, by Hartree<sup>8</sup> using a self-consistent field method of determining the radial charge distribution, and by Slater<sup>9</sup> from wave mechanics using an approximate solution of the wave equation of an electron. Brindley<sup>10</sup> has shown that the Slater method gives results in best agreement with experimental susceptibilities for most atoms and ions, and in particular, for those with the larger values of  $r$  to which class the thallous ion belongs. Slater's rules for determining the screening constants for the various electrons in an atom or ion have been applied to obtain a theoretical value for the susceptibility of the thallous ion. Using this method, for any electron

$$f^2 = \frac{(n')^3(n' + \frac{1}{2})(n' + 1)}{(Z - s)^2}$$

where  $n'$  is the effective principal quantum number and  $Z - s$  the effective nuclear charge for each electron considered,  $Z$  being the atomic number and  $s$  the appropriate screening constant derived for any electron by considering the screening effects on it of other electrons in the atom, using Slater's rules. The susceptibility is obtained by

<sup>7</sup> Pauling, *Proc. Roy. Soc.*, 1927, 181.

<sup>8</sup> Hartree, *Proc. Camb. Phil. Soc.*, 1928, 111; *Proc. Roy. Soc.*, 1933, 141.

<sup>9</sup> Slater, *Physic. Rev.*, 1930, 57.

<sup>10</sup> Brindley, *Phil. Mag.*, 1931, 786.

summing over all the electrons in the ion. When  $\bar{r}^2$  is expressed in atomic units (multiples of  $a_0$ , the radius of the Bohr orbit in normal hydrogen =  $0.528 \times 10^{-8}$  cm.) then

$$\chi_A \times 10^6 = -2.83 \times 10^{10} (0.528 \times 10^{-8})^2 \cdot \sum \frac{(n')^2(n' + \frac{1}{2})(n' + 1)}{(Z - s)^2}$$

$$= -0.790 \sum \frac{(n')^2(n' + \frac{1}{2})(n' + 1)}{(Z - s)^2}.$$

The appropriate values for the thallous ion are shown in Table III. whence  $-10^6 \chi_A = 79.99 \times 0.790 = 63.19$ , the theoretical atomic susceptibility of the thallous ion.

It will be seen that the theoretical and experimental susceptibility values are of the same order of magnitude, but the experimental value is rather less than two-thirds of the theoretical value. The calculated value is that for the free ion, whereas the experimental value is derived from measurements on the crystalline solid, and therefore, as considered previously, may to some extent be lower due to interionic forces, but these effects should only cause a difference of some 3.8 per cent. A real discrepancy between experiment and theory is therefore indicated by the above results. This is supported by Brindley's results<sup>10</sup> for a number of other atoms and ions. He has shown that there is an increasing divergence between theoretical and experimental susceptibilities with increasing atomic weight of the element concerned. This point will be further considered later.

### Ionic Radius.

From the experimental atomic susceptibility the value of  $\Sigma \bar{r}^2$  can be evaluated by means of the Langevin equation, giving for the thallous ion  $\Sigma \bar{r}^2 = 48.49$  in atomic units, or  $13.44 \times 10^{-16}$  in absolute units. The value  $\Sigma \bar{r}^2 = 48.49$  is to be compared with the value of 79.99 deduced from theory. This average mean square radius or effective electron density distribution is, of course, not the square of the outer radius, but a composite factor depending on all the extra-nuclear electrons in the ion. A value for the actual outer radius cannot be obtained directly from this since there is no direct means of determining the contributions of the various shells to this factor. Although the outer (6s) shell will contribute a large proportion of the susceptibility, Table III. shows that

Total $\Sigma \bar{r}^2$				79.99

the 5*d* shell in the case of the thallous ion also contributes a large amount. By making use of the theoretical values in Table III. the radius of the outer shell can be estimated from the experimental susceptibility. Slater,<sup>9</sup> has shown that the effective radial electron density (and hence a measure of the radius), of any shell is given by the formula  $\bar{r}' = \frac{(n')^2}{(Z-s)}$ .

Applying this to the 6*s* shell, with the appropriate value of  $(Z-s)$ , gives for the thallous ion the value  $\bar{r}'$  (theoretical) = 1.78 A.U. It has already been pointed out that the theoretical susceptibility is too high, therefore this value of the radius of the outer shell will be correspondingly too large. A value of  $\bar{r}'$  from experimental data may be estimated from the value of  $\Sigma \bar{r}^2$  derived from the experimental susceptibility as follows:—

Since  $\sqrt{\Sigma \bar{r}_e'^2} : \sqrt{\Sigma \bar{r}_i'^2} :: \bar{r}_e' : \bar{r}_i'$  (where  $\bar{r}_e'$  and  $\bar{r}_i'$  are the radii of the outer shell, or orbit, given by experimental and theoretical data respectively, and  $\Sigma \bar{r}_e'^2$  and  $\Sigma \bar{r}_i'^2$  are the corresponding average mean square radii)

$$\text{then } \bar{r}_e' = \frac{\sqrt{48.49}}{\sqrt{79.99}} \times 1.78 = 1.38 \text{ A.U.}$$

Goldschmidt's value for the ionic radius of the thallous ion from X-ray data is 1.49, slightly higher than the value from the susceptibility data. Bearing in mind the uncertainty of the theory involved in estimating the value 1.38 from the experimental susceptibility, this may be taken to be in good agreement with Goldschmidt's value.

### Slater Wave Functions and Ionic Susceptibilities.

Brindley<sup>10</sup> has shown that Slater's wave functions can also be applied to estimate the proportion of the molar susceptibility of a compound that is contributed by the constituent ions when these are simple mono-nuclear systems. It is thus possible from the experimental molar susceptibilities of those thallous compounds with single anions to deduce a value for the ionic susceptibilities based on the theoretical deduction that these are proportional to the average mean square radii of the ions concerned, as follows:—

$$\chi_A(\text{Ti}') : \chi_M :: \Sigma \bar{r}^2(\text{Ti}') : \Sigma \bar{r}^2(\text{Ti}') + \Sigma \bar{r}^2_{\text{anion}}$$

$$\therefore \chi_A(\text{Ti}') = \frac{79.99 \times \chi_M}{79.99 + \Sigma \bar{r}^2_{\text{(anion)}}}$$

TABLE IV.—IONIC SUSCEPTIBILITIES.

$\Sigma \bar{r}^2$  for Thallous ion calculated by Slater method = 79.99 in Atomic Units.

Table IV. shows the results obtained in this way for the six compounds of this type that were investigated. The values of  $\Sigma\tilde{r}^2_{(\text{anion})}$  in column 3 are taken from Brindley's values in the case of the chloride, bromide and iodide ions, and have been calculated similarly for the fluoride and sulphide ions. The values in column 5 are given by:

$$\chi(\text{anion}) = \chi_M - \chi(\text{Ti}^+).$$

It will be noted that the average value  $-10^6\chi_A = 40.14$  for the ionic susceptibility of the thalious ion, deduced in this way is somewhat higher than that from purely experimental data. Table V. shows

values for the atomic susceptibilities of the positive and negative ions collected together from various sources for comparative purposes. This table shows that application of the Slater rules to assess the relative contributions of the positive and negative ions to the molar susceptibility in thalious compounds gives higher values for the positive ion and lower values for the negative ions than any other method. This agrees with the previous evidence that the theoretical value of  $\Sigma\tilde{r}^2$  and hence of the diamagnetic susceptibility of the thalious ion is too high, again suggesting a need for a modification of the theory.

TABLE VI.—VALUES OF  $\Sigma\tilde{r}^2$  FOR THE VARIOUS SHELLS.

	6s <sup>2</sup> .	5d <sup>10</sup> .	5s <sup>2</sup> , p <sup>6</sup> .	4f <sup>14</sup> .	4d → 1s, p Inclusive.	Total $\Sigma\tilde{r}^2$ .
Mercury . . .	45.55	45.97	5.76	4.93	3.05	105.3
Thallium . . .	30.10	37.12	5.28	4.59	2.90	80.0
Lead <sup>++</sup> . . .	21.37	30.59	4.87	4.29	2.57	63.7

Further light as to where this modification must be applied is given by a consideration of the adjacent elements in the periodic table, namely, mercury and lead. Thus, unionised mercury and the thalious and plumbous ions are electronic isomers, containing identical electronic shells and differing only in atomic number. The theoretical values of

$\Sigma f^2$  for mercury and the plumbous ion, calculated by Slater's method, are shown in Table VI. giving 83.18 and 50.31 respectively, for the atomic susceptibilities, expressed in the usual units (*i.e.* all values are multiplied by  $-10^6$ ). The corresponding experimental values are 38.75 for mercury, calculated from Honda's value of 0.193 for the mass susceptibility of liquid mercury at room temperature, and 44.3 for the plumbous ion. This latter value has been calculated from the mass susceptibilities for plumbous compounds quoted in the International Critical Tables, VI., p. 357, applying the appropriate corrections for the negative ions as in Table I. Comparing these theoretical and experimental values with those for the thallous ion, namely 63.2 (theoretical) and 38.3 (experimental), it will be seen that the discrepancy between theory and experiment is greatest for the element of lowest atomic number, *i.e.*, mercury. Examination of the values of  $\Sigma f^2$  for these three elements (Tables III. and VI.), shows that the susceptibility is in all three cases predominantly due to the ten  $5d$  and the two  $6s$  electrons. It is apparent, therefore, that the Slater rules give too high a value for the contribution of these shells to the diamagnetic susceptibility. The experimental atomic susceptibility of the plumbous ion is probably slightly high due to the tendency to covalency in its compounds. If the compounds were strictly polar the value would probably be about 38.0, by comparison with the corresponding values for mercury and lead, since there should be a slight decrease in the ionic susceptibility caused by the increase of the atomic charge  $Z$ . Allowing for this, the difference between the values of the theoretical and experimental susceptibilities is of the order 45 units for mercury, 25 units for thallium and say 12 units, or thereabouts, for lead. These differences represent a series of the type  $(a+b)^2$ ,  $(a)^2$ ,  $(a-b)^2$ . In Slater's formula for the susceptibility the only squared factor is  $(Z-s)$ , which will vary in the above way on passing from mercury to lead. It may then be inferred that the discrepancy between experiment and theory lies in the value of  $s$  the screening constant in Slater's formula. Thus, for either or both of the  $5d$  and  $6s$  shells the screening constant is too high, and hence the effective atomic number  $(Z-s)$  is too low. Owing to this factor being squared in the formula, the deviation between theory and experiment will appear most marked for the element of least atomic number, namely, mercury. Angus<sup>11</sup> has suggested a modification in the method of grouping the  $s$  and  $p$  electrons, giving a slightly different value of the screening constant for these electron groups. In the case of the thallous ion this was found to make a difference of only one or two units to the theoretical susceptibility since it does not affect the values of  $\Sigma f^2$  for the  $5d$  and  $6s$  shells. This, therefore, does not explain the discrepancy, and the results given for the experimental susceptibility of the thallous ion support Brindley's view, based on theoretical considerations, that Angus' method is not justifiable. Some other modification which will explain all the above points seems to be needed in the theory.

### Summary.

1. The magnetic mass susceptibility of 27 thallous compounds has been determined and a mean value of  $-38.4 \times 10^{-6}$  obtained, from the salts with univalent anions, for the ionic susceptibility of the thallous ion.

<sup>11</sup> Angus, *Proc. Roy. Soc.*, 1932, 569.

2. Salts with divalent and trivalent anions give a slightly lower value, and salts with organic anions a higher value, explained as due to alteration in the ionic radius with change in co-ordination number.
3. The mass susceptibility of a number of potassium salts has also been determined to obtain correcting constants for the anions.
4. The theoretical atomic susceptibility has been calculated from Slater's approximate wave functions and is compared with the experimental value, which is considerably lower, indicating a discrepancy between theory and experiment.
5. A value of the ionic radius  $1.36 \text{ \AA.U.}$  has been deduced from the experimental atomic susceptibility and is compared with the value  $1.49 \text{ \AA.U.}$  obtained from X-ray crystallography.
6. The Slater method as applied by Brindley has been used to determine the relative contributions of the positive and negative ions in the salts with single univalent anions and again indicates too high a theoretical value for the atomic susceptibility of the thallous ion.
7. Comparison of the atomic susceptibility of the thallous ion with those for mercury and the plumbous ion indicate that the discrepancy between theory and experiment is due to too high a value for the screening constants of the  $5d$  and  $6s$  levels, given by Slater's method.

## ON THE RATE DETERMINING STEP IN THE DIFFUSION OF HYDROGEN THROUGH PALLADIUM.

BY ADALBERT FARKAS.

*Received 5th August, 1936.*

The notion that hydrogen can diffuse through metals, especially through palladium, is not new. It was early recognized that in this diffusion, there are two different types of processes: one occurring on the gas-metal boundary, the other within the metal.

Wagner<sup>1</sup> showed that the laws governing the diffusion of hydrogen into palladium differ according to whether the process on the boundary or that inside the metal is the rate governing step. This question has also been discussed by Melville and Rideal<sup>2</sup> who, among other things, investigated experimentally the diffusion of hydrogen and deuterium through palladium. The novelty of the present investigation lies in the fact that it has proved possible to investigate simultaneously the processes occurring both on the boundary and inside the metal. The principle of the method is as follows:—

Take a palladium disc, one side of which is in contact with hydrogen at a certain pressure, the gas being removed continuously by pumping from the other side. In the stationary state the concentration of hydrogen in and on the disc can be represented by Fig. 1. From each cross-section in the disc there will be a diffusion in the forward direction

<sup>1</sup> C. Wagner, *Z. physik. Chem., A*, 1932, **159**, 459.

<sup>2</sup> H. W. Melville and E. K. Rideal, *Proc. Roy. Soc.*, 1935, **153**, 89, 103.

(i.e., towards the vacuum side) and also in the backward direction. The quantity usually measured in diffusion experiments is the net diffusion leaving the disc at the vacuum side (i.e. C). It is desirable to measure the backward diffusion (i.e. B) since obviously, its magnitude compared with the net diffusion is important in deciding which of the two reactions

FIG. 1.—Concentration of hydrogen in a palladium disc in the diffusion process.

governs the rate of the diffusion through the metal; if it is very much larger than the net diffusion the reaction inside the metal is the slow process, whereas if it is comparable with the net diffusion the rate is then at least partly determined by the process at the boundary. The backward diffusion can be measured if parahydrogen (or orthodeuterium) is used instead of normal hydrogen for the diffusion experiments. In the reaction at the boundary every hydrogen molecule is dissociated (or at least the bond is sufficiently labile to ensure an *ortho-para*-conversion), and thus every molecule returning into the gas phase from the boundary layer by the process of back diffusion will be normal hydrogen and the rate of the *para*-conversion induced by the

metal surface can be used as a measure for the back diffusion. Since the *para*-conversion occurring in the gas phase and the amount of gas diffusing right through the metal can be measured simultaneously, from one single experiment carried out in this way, we can draw conclusions as to the mechanism of the diffusion process.

### Experimental Arrangement.

Two series of experiments were carried out, one with a palladium disc and another with a palladium tube. The palladium disc (*cf.* Melville and Rideal<sup>2</sup>) (10 mm in diameter, 0.1 mm. thick) was welded to a platinum ring which in turn was sealed into a glass tube. Both the disc and the tube (10 cms. long, 2 mm. in diameter, 0.1 mm. wall) were used in the same arrangement as by Melville and Rideal. The disc was used in a horizontal position. The rate of diffusion was determined by measuring the decrease of the pressure by a Bourdon gauge. The *ortho-para*-conversion was followed by extracting small samples and determining the concentration by the usual microconductivity method.<sup>3</sup> By suitable connections the diffusion from either the disc or the tube could be investigated by admitting the gas alternately to the two sides. The *ortho-para*-conversion on both sides of the disc or tube could be investigated in the same way. The separate investigation of both sides, though giving the same results so far as diffusion is concerned, was important for studying the reactions at the boundary.

The palladium tube or disc was heated in a small electric furnace, the temperature being measured by a thermometer. Two U-tubes kept at liquid-air temperatures prevented the palladium from coming into contact with grease and mercury vapour.

In all diffusion experiments particular care was taken that the stationary

<sup>2</sup> A. Farkas, *Z. physik. Chem., B.*, 1933, 22, 344.

state was actually obtained, *i.e.* the palladium was saturated with hydrogen. To ensure this, in most experiments (especially at lower temperatures) the palladium was first saturated, by leaving it in contact with hydrogen from both sides until no change of pressure was noticeable. Then the gas was rapidly pumped off from one side and the progress of diffusion measured. In these experiments the rate of the *para*-conversion was determined in a parallel run.

Since the volume of the connections was comparable with that of the tube containing the palladium care was also taken to ascertain that the rate of the *ortho-para*-hydrogen conversion should not appear to be reduced by insufficiently rapid diffusion between the palladium and the sampling tap.

### Experimental Results with the Disc.

The progress of the diffusion of hydrogen through the palladium disc is shown graphically in Fig. 2, the square root of the pressure being plotted against time. In the pressure region investigated the amount of gas diffusing is proportional to the square root of the pressure.

The *para*-conversion proceeded strictly according to the formula

$$u_t = u_0 e^{-kt}$$

$u_t$  and  $u_0$  denoting the excess concentration of *para*-hydrogen at time  $t$  and  $t = 0$  and  $k$  a constant.

For the sake of comparison we will characterise

FIG. 2.—Diffusion of hydrogen through a palladium disc (original state). The numbers in the circles denote the numbers of the experiments.

the rate of diffusion and conversion of *parahydrogen* by their respective half-life periods, *i.e.* the time in which the pressure has decreased from say 20 mm. to 10 mm. Hg inside the diffusion vessel or in which half of the *parahydrogen* has been converted into normal. The half-life periods for the diffusion rate were taken from figures like Fig. 2.

Table I. shows the half-life periods

for the diffusion and conversion rates.

These results reveal that the rate of the *para*-hydrogen conversion is :

FIG. 3. — Diffusion of hydrogen through the palladium disc after oxidation and successive reduction.

lower side of the palladium disc before the activation, and curve IV to the diffusion rate after the activation. A close connection between the diffu-

FIG. 4.—The rate of diffusion and *ortho-para*-conversion in dependence of temperature. Disc in original state:—

- I = rate of diffusion, energy of activation 5.4 Kcals.
  - II = rate of conversion on the upper side of the disc, energy of activation 5.8 Kcals.
  - III = rate of conversion on the lower side, energy of activation 2.3 Kcals.
- After oxidation and reduction:
- IV = rate of diffusion, energy of activation 3.1 Kcals.

sion through the unactivated disc and the conversion on its upper side, will again be observed, the corresponding curves I and II being nearly

parallel and indicating similar energies of activation namely 5.4 Kcals. for the diffusion and 5.8 Kcals. for the *para*-H<sub>2</sub> conversion. The energies of activation (*A*) were obtained from the dependence of the half-life period ( $\tau$ ) on temperature according to the formula

$$\frac{d \log \tau}{dT} = - \frac{A}{RT^2}$$

On the other hand, curve III, characterising the conversion on the lower side, has a much smaller slope than I and II, showing that the activation energy for the conversion or dissociation of hydrogen on this side is much slower than on the other, namely 2.3 Kcals. Similarly the slope of IV, indicating the diffusion rate after the activation, is smaller than that of I, showing that after the activation the energy of activation has decreased from the original 5.4 Kcals. to 3.1 Kcals.

### Experimental Results with the Tube.

Experiments performed with the palladium tube confirmed essentially the results obtained from the experiments with the palladium disc.

In the first series of experiments the tube was used after having been degassed at 350° C. but without any other treatment. The results are

FIG. 5.—The rate of diffusion and of *ortho-para*-conversion in dependence of temperature. Tube in original state :

- I = rate of diffusion, energy of activation 5.6 Kcals.
- II = rate of conversion on inner side, energy of activation 5.4 Kcals.
- III = rate of conversion on outer side, energy of activation 9.6 Kcals.

summarised in Fig. 5 the logarithm of the half-life periods for the diffusion, for the conversion on the inner and on the outer side of the palladium tube being characterised by the curves I, II and III respectively. Each point marked on the figure was again obtained from Figs. like 2 and 3. It will be noticed that the diffusion rate goes parallel with the rate of conversion

on the inner side of the tube, the latter rate being again 3 to 4 times faster.

The crossing of curves II and III at about 40° C is remarkable: above this temperature the conversion is faster on the outer side of the tube. This is due to the fact that the rate of conversion (or in general any heterogeneous reaction) depends on an energy of activation and on the magnitude of the surface available for catalysis. A hindrance of the reaction rate by a high energy of activation can be compensated by a large surface area and vice versa. The slope of the steeper line corresponds to an energy of activation of 9.6 Kcals., that of the other to an energy of 5.4 Kcals. Since this difference in the energies of activation would at 40° C make the conversion proceed  $e^{-\frac{4200}{813R}} = 1000$  times more slowly, there must be a correspondingly larger area available on the outer surface to bring about a conversion rate equal on both sides.

The rates for the diffusion and conversion were quite reproducible as is seen by comparing Figs. 5 and 6. The results of the experiments summarised in curves I (diffusion) and II (conversion on the inside) do not differ appreciably from those contained in Fig. 5, although there was an interval of several days between the two series of experiments.

On the other hand it was again found that by oxidation (50 mm. of O<sub>2</sub> at 320° C for an hour) and subsequent reduction the rates of both diffusion and conversion were increased (cf. Fig. 6 curves III for diffusion and IV for conversion on the inside). In this case, however, the rate of conversion was only twice as fast as the rate of diffusion, and it was not possible even after a second activation by oxidation and reduction) to obtain on the inner side

FIG. 6.—Diffusion and conversion on the tube some days later than Fig. 5.

I = rate of diffusion, energy of activation 6 Kcals.

II = rate of conversion on inner side, energy of activation 4.5 Kcals.

Tube oxidised and reduced:

III = rate of diffusion, energy of activation, 4.2 Kcals.

IV = rate of conversion on inner side, energy of activation 4.1 Kcals.

of the tube such a high activity as is shown on the outer side, owing probably to the presence of some non-volatile impurity in the tube.

### The Comparison of the Rates of Diffusion for H<sub>2</sub> and D<sub>2</sub>.

In a previous paper by A. and L. Farkas<sup>4</sup> the relative rates for the diffusion of hydrogen and deuterium were investigated by allowing a mixture of hydrogen and deuterium to diffuse through a palladium tube and determining the composition of the diffusing gas. The ratio  $(H/D)_{diff.}/(H/D)_{orig.}$  characterising the relative diffusion rates of hydrogen and deuterium, where  $(H/D)_{diff.}$  and  $(H/D)_{orig.}$  denote the ratio of hydrogen and deuterium in the diffused gas and in the original gas respectively) was higher than unity and varied with temperature. The temperature variation was explained by assuming that the energy

<sup>4</sup> A. Farkas and L. Farkas, *Proc. Roy. Soc.*, 1934, 144, 467.

of activation for the diffusion of hydrogen and deuterium differs by some 800 cals.

Jost and Wiedemann<sup>5</sup> who compared directly the diffusion rates of hydrogen and deuterium into a palladium sphere could not substantiate this dependence of the relative rates on temperature, but showed that the ratio for the diffusion of hydrogen and deuterium is very nearly  $\sqrt{2}$ , i.e. the value to be expected from their different masses. These authors also pointed out the necessity, according to Wagner, of ascertaining whether the diffusion rate is governed by the boundary process or not. They assumed that by palladising their sphere they made the surface sufficiently active to eliminate the surface reaction. No direct comparison of their experiments with those of A. and L. Farkas was possible since the latter undoubtedly involved a surface reaction having a very much higher activation energy (17 Kcals.) than in Jost and Wiedemann's experiments (5 Kcals.). On the other hand the direct comparison of the diffusion rates of hydrogen and deuterium through a palladium tube by Melville and Rideal<sup>2</sup> yielded results comparable with those of A. and L. Farkas.

It seemed desirable, therefore, to compare again the relative diffusion rates for the hydrogen isotopes, particularly since by using the very permeable palladium sample the investigations could be extended over a wider range of temperature and, moreover, by comparing not only the diffusion rates but also the conversion rates for the hydrogen isotopes it should be possible to decide whether the process on the boundary or that in the bulk of the palladium was responsible for the different diffusion rates.

In the diffusion experiments *ortho*-deuterium was used (containing about 90 per cent D) and the rate of its conversion determined in the usual way. The results of the experiments comparing the diffusion rates and conversion rates for the hydrogen isotopes is summarised in Tables II. and III.

From these experiments we conclude that:

1. The ratio of the diffusion rates of hydrogen and deuterium through palladium is only slightly dependent on temperature and varies from 1.24 to 1.84 in the temperature region of 186 to 20° C.

2. The ratio of the conversion of *para*hydrogen and of *ortho*deutrium is about the same.

3. The energies of activation for the diffusion of hydrogen and deuterium determined from the dependence of the diffusion rate on temperature are equal within the limits of experimental error, being 5.4 and 5.3 Kcals. respectively.

TABLE II.—COMPARISON OF ENERGIES OF ACTIVATION FOR DIFFUSION. DISC (ORIGINAL ACTIVITY).

### Discussion.

A complete theoretical treatment of the diffusion of hydrogen through palladium is complicated for two main reasons: (1) The actual process

of diffusion consists of several different individual processes. (2) The two sides of a palladium sample are in general not identical, so far as catalytic activity is concerned, and processes occurring on different sides involve different velocity constants.

We shall consider now, however, only simplified cases, in order to find out the characteristics of the diffusion process, such as dependence on pressure and on temperature. Thus it will be assumed that there are only three different processes on the boundaries and in the bulk of the metal:

(a) Sorption of hydrogen on the surface of the metal involving a dissociation of molecular hydrogen into atoms;

(b) Diffusion of the hydrogen atoms from one boundary to the other through the bulk of the metal;

(c) Desorption of hydrogen from the boundary involving a recombination of molecules from the atoms.

The term "sorption" is used here to designate the boundary reaction which has a hydrogen molecule in the gaseous phase as initial state and dissociated hydrogen on or beneath the surface of the metal as final state, the term "desorption" being used for the reverse reaction. Thus no discrimination is made between two or more consecutive processes occurring on the boundary, such as "activated adsorption" in the sense of H. S. Taylor<sup>6</sup> (transfer of hydrogen molecules from the gas phase to the surface of the metal, involving some loosening of the molecular bond) followed by "penetration" used by Melville and Rideal<sup>4</sup> (a boundary process involving transfer of hydrogen atoms from the surface into the first layer inside the metal). Melville and Rideal assume from recent experiments of Roberts<sup>7</sup> that the actual process of adsorption, even if involving a breakage of molecular bonds, has a negligible energy of activation and they regard penetration as the process characteristic for the boundary. If this assumption can be made generally their term "penetration" has the same meaning as the term "sorption" used in this paper.

<sup>6</sup> H. S. Taylor, *J. Am. Chem. Soc.*, 1930, **52**, 5298; 1931, **53**, 578.

<sup>7</sup> J. K. Roberts, *Proc. Roy. Soc.*, 1935, **152**, 445.

As a further simplification a possible difference in the activity and effective area of the two metal/gas boundaries will be neglected. Thus, assigning to the above-mentioned processes the velocity constants  $k_a$ ,  $k_b$ , and  $k_c$ , denoting by  $x$  and  $y$  the concentration of the atoms on the boundaries and by  $C$  the concentration of hydrogen in the gas phase we find

$$\begin{aligned} k_a C &= k_c x^2 + k_b(x - y) \\ k_b(x - y) &= k_c y^2 \end{aligned}$$

where  $k_c x^2$  is the observed rate of the *para*-hydrogen conversion and the expression  $k_b(x - y)$  arises since the net diffusion is equal to difference of the forward and backward diffusion. This is the quantity actually observed in diffusion experiments.

In examining the effect of pressure we have to distinguish two limiting cases:

(1) The diffusion is very slow compared with the rate of the adsorption and desorption, i.e.  $y \ll x$  therefore

$$x = \sqrt{\frac{k_a C}{k_c}}$$

or the net diffusion

$$k_b x = k_b \sqrt{\frac{k_a C}{k_c}}$$

is proportional to the square root of the concentration or pressure.

(2) The diffusion is very rapid, i.e.  $y \approx x$  then

$$k_a C = 2k_c x^2$$

or the net diffusion

$$k_c x^2 = \frac{k_a C}{2}$$

is proportional to the concentration or pressure.

It was found experimentally that the diffusion is proportional to the square root of the pressure, but this result must be regarded as merely accidental since in most experiments none of the conditions is strictly fulfilled under which this simple relationship is to be expected: both boundaries generally have distinctly different activities and the net diffusion is of the same order of magnitude as the adsorption or the *para*-hydrogen conversion. Only in the experiments with the activated palladium disc (Nos. 25 to 28, Fig. 4) are the reactions on the boundaries sufficiently rapid to explain the square root law.

The next question is the relation between the energies of activation of the processes observed experimentally, i.e. conversion of *para*-hydrogen and net diffusion, and those of the individual processes of sorption, diffusion of atoms and desorption.

Even in the general case, when the activity is different on different sides of the palladium sample, the sum of the rate of conversion plus net diffusion is the rate of adsorption. Thus we can obtain the energy of activation ( $A_a$ ) for this process from the dependence of the mentioned sum on temperature.

Since the conversion is always larger than the diffusion and furthermore the dependence of the net diffusion on temperature is nearly the same as that of the conversion we find as energy of activation for the sorption process the same value as the energy of activation for the conversion.

The difference between the energies of activation for desorption ( $A_d$ ) and sorption is the heat of adsorption. This quantity is probably of the order of 2 Kcals., *i.e.* near the value of the heat of absorption (*cf.* Melville and Rideal<sup>2</sup> and Sieverts and Zapf.<sup>3</sup>).

The energy of activation for the actual diffusion of the atoms through the bulk of the metal ( $A_b$ ) can be obtained as follows from the experiments with the activated disc (Nos. 25 to 28). The diffusion being very much slower than the conversion, we obtain for the net diffusion

$$k_b x = k_b \sqrt{k_a C / k_c}$$

or since

$$k_a \propto \exp(-A_a/RT), k_b \propto \exp(-A_b/RT) \text{ and } k_c \propto \exp(-A_c/RT)$$

$$k_b x \propto \exp[(-A_b + Q/2)/RT]$$

Consequently the true energy of activation for the atomic diffusion is higher by half the heat of sorption than the apparent energy of activation for the diffusion observed on the activated disc.

With  $Q = 2$  Kcals. we obtain an energy diagram as shown on Fig. 7 for the palladium disc in its original state (*i.e.*, before the activation). Since the hydrogen diffuses within the metal in atomic form, the figure refers to  $\frac{1}{2}H_2$  and therefore only half of the energy of activation for the sorption  $A_a'$  and  $A_a''$  appears on the boundaries; *i.e.*, 2.9 and 1.15, instead of 5.8 and 2.3 Kcals. (*cf.* page 1670).

This energy diagram is modified after the activation of the palladium disc; the energy barrier on the left-hand side connected with the sorption and dissociation of hydrogen is considerably decreased (shown in Fig. 7 by the dotted line) and the rate of diffusion is determined by the highest barrier, *viz.* that connected with the transfer of hydrogen atoms in the bulk of the metal.

It seems justifiable to assume that inside the palladium the energy barrier is the same before and after activation, since by the superficial oxidation and reduction the surface properties alone and not the interior of the metal have been altered.

FIG. 7.—Energy diagram for the diffusion of hydrogen through the palladium disc (original state):

$A_a'$  = energy of activation for sorption on the upper side.

$A_a''$  = energy of activation for sorption on the lower side.

$A_b$  = energy of activation for diffusion.

$Q$  = heat of sorption.

<sup>3</sup> A. Sieverts and G. Zapf, *Z. physik. Chem.*, A, 1935, 174, 359.

With the palladium tube we have essentially the same state of affairs. If we assume the same conditions inside the bulk of the tube as has been found for the disc, the energy barriers for the tube can be represented as those in Fig. 7 with  $A_a' = 9.6$  and  $A_a'' = 5.4$  Kcals. One difference, however, must be mentioned. It is not the higher barrier of 9.6 Kcals. which determines the rate of diffusion of hydrogen but the lower one of 5.4 Kcals., since, as already mentioned, the strong hindrance of the boundary reaction caused by the high energy of activation appears to be over-compensated by a very large effective area (or some other factor independent of temperature).

We consider finally the different rates of diffusion for  $H_2$  and  $D_2$ . This difference is caused either by different molecular (or rather atomic) velocities on and inside the metal, due to the difference in the masses, or by a difference in the energies of activation.

In the former case the dependence of the ratio on temperature should be less than that observed. In the latter, a difference in the energies of activation for the diffusion of  $H_2$  and  $D_2$  of 200-300 calories would account for the absolute value of the ratio, though its dependence on temperature would suggest a difference of 660 cal. Assuming this value the ratio of the diffusion rates of the two hydrogens ( $v_H/v_D$ ) is formally represented by the expression (cf. Table IV.).

$$v_H/v_D = 0.6 e^{-660/RT}$$

though it is not quite clear why the factor 0.6 occurs.

It is difficult to decide which explanation is correct, since, owing to the relatively small dependence of the rates on temperature and the possible experimental error, the variation actually observed may only be accidental.

Moreover, from the formula opposite a higher ratio is to be expected for the conversion velocities of *parahydrogen* and *orthodeuterium* at  $-30^\circ \text{C}$ . than is observed (see Table III).

It is therefore not easy to determine with certainty the cause of a difference in reaction velocity from a mere comparison of the velocities of heterogeneous reactions involving the hydrogen isotopes and their compounds.

TABLE IV.

Temperature $^\circ \text{C}$ .	Ratio	
	Observed.	Calculated.
186	1.24	1.25
131	1.36	1.37
106	1.40	1.45
20	1.84	1.87

### Conclusions.

From the present results we can understand why hydrogen diffuses so rapidly through metals in electrolysis; the hydrogen is supplied to the metal in atomic form and thus the hindrance due to the energy of activation for dissociation is eliminated (see Fig. 7). Furthermore it is also evident that the actual heights of the barrier on either side of the metal do not determine the diffusion rate, provided that the barrier on the entrance side is not lower than that on the outlet side. Owing to the supply of atomic hydrogen the bulk of the metal becomes saturated and then the hydrogen "overflows" over the edge of the outlet barrier.

This picture serves to explain some observations of Kobosew and

Monblanowa<sup>9</sup> on the effects of electrolytes and poisons on the electro-diffusion of hydrogen through a palladium membrane. Electrolytes, (specially  $K^+$  ions) and poisons (such as pyridine or sodium arsenate) accelerate the rate of diffusion if applied on the entrance side of the membrane but have an inhibiting effect if applied on the other side. A poisoning of the entrance side prevents the atoms from recombining and thus forces them to leave the metal through diffusion, on the other hand, a blocking up of the exit side must necessarily lead to a backward diffusion, so that more and more hydrogen will leave the membrane on the same side as entered.

Melville and Rideal<sup>8</sup> obtained the apparent energies of activation shown in Table V. for the diffusion of hydrogen through a palladium disc and tube with and without an electro-deposited surface layer of copper and nickel.

TABLE V—ENERGY OF ACTIVATION IN KCALS.

	Uncovered.	0.0034 cm. Cu.	0.00038 cm. Ni.
Tube .	17.8	13.7	14.3
Disc .	5.0	11.4	—

The considerable effect of the coating is to be attributed entirely to a change in the surface conditions of the palladium, since naturally by

the electro-deposition of the Cu or Ni-layer the inside of the palladium has not been changed at all.

Finally a group of experiments by Coehn and co-workers<sup>10</sup> carried out on wires, one portion of which was saturated electrolytically with hydrogen, allows a direct determination of the energy of activation for the actual diffusion inside the palladium. The spreading of hydrogen inside the wire was followed up by measuring the change in the electric resistance or potential of certain portions of the wire. From the dependence of the coefficient of diffusion on temperature one finds an energy activation of 4.9 to 6.7 Kcals. These figures are actually characteristic of the transfer of hydrogen inside the metal, no processes on the boundaries being involved, and are in satisfactory agreement with the value of 4 Kcals. obtained in this paper (see Fig. 7).

### Summary.

The rate of diffusion of hydrogen through a palladium disc and tube has been compared with the rate of the conversion of *para*-hydrogen at temperatures of 20 to 320° C. and about at 20 mm. Hg.

Applying this method one can decide whether and to what extent the reactions occurring on the metal/gas boundaries determine the rate of diffusion.

Two characteristic cases were isolated: The *para*-hydrogen conversion is (1) about 3-4 times quicker than the diffusion and its dependence on temperature is approximately the same as that of the diffusion; (2) very much faster than the diffusion and has a smaller temperature coefficient than the diffusion.

In the former case the boundary reaction is the rate-determining step for the diffusion and consists in a dissociation of the hydrogen molecule, being also responsible for the conversion of *para*-hydrogen; in the latter,

<sup>9</sup> N. I. Kobosew and W. W. Monblanowa, *Acta Phys.-Chem. U.S.S.R.*, 1934, 1, 611.

<sup>10</sup> A. Coehn and co-workers, *Z. Physik*, 1930, 62, 1; 1931, 71, 179; 1933, 83, 291.

the rate of diffusion is governed by the actual transfer of the hydrogen atoms in the bulk of the palladium.

Though the rate of diffusion does not depend on the direction of diffusion, the rate of the *para*-hydrogen conversion may be different on different sides of the disc or tube, indicating the two sides may have entirely different catalytic activities.

From the apparent energies of activation for the *para*-hydrogen conversion on both sides of a palladium sample and the energy of activation for the diffusion (calculated from the dependence of the corresponding rates on temperature) the energy levels for the primary processes occurring in the diffusion can be determined. Such processes are (1) The sorption of molecular hydrogen involving dissociation; (2) transfer of atomic hydrogen through the bulk of the palladium; (3) desorption of molecular hydrogen. For example the following energies of activation were found for a palladium disc with sides of different activity for sorption (entrance side) 5.8 Kcals.; for transfer 4.1 Kcals.; for desorption (exit side) 3.3 Kcals. Rate determining step = Sorption.

A comparison of the rates of diffusion for hydrogen and deuterium shows that the former diffuses slightly more quickly, but the cause of this behaviour cannot be given with certainty.

Some recent experiments on the diffusion of hydrogen through palladium are discussed in the light of these results.

The author has great pleasure in expressing his gratitude to Professor E. K. Rideal, F.R.S., for the privilege of working in his laboratory and for many enlightening discussions. He is also indebted to the Imperial Chemical Industries, Ltd., for a grant.

## TEMPERATURE COEFFICIENTS OF ELECTRICAL CONDUCTIVITY OF ELECTROLYTES IN METHYL AND ETHYL ALCOHOLS.

BY ALEXANDER G. OGSTON.

*Received 27th August, 1936.*

The present work is concerned with the measurement of the electrical conductivities of solutions of certain salts, bases and of hydrogen chloride in methyl and ethyl alcohols at 25°, 15° and 4° C., and the conclusions which may be drawn from the results. From the conductivity curve of an electrolytic solution it is possible to obtain the limiting conductivity at infinite dilution ( $\Lambda_0$ ) and the degree of deviation of the curve from the theoretical Debye-Hückel-Onsager straight line. Fuoss and Krauss<sup>1</sup> have given a method by which, assuming the deviation to be due to incomplete dissociation of the electrolyte,  $\Lambda_0$  and a consistent "true" dissociation constant ( $K$ ) may be calculated. By obtaining values for these quantities over a range of temperature the variation of  $\Lambda_0\eta$  may be measured ( $\eta$  being the viscosity of the solution), also the mean heat of dissociation of the electrolyte: the former may be used to test Walden's rule (constancy of  $\Lambda_0\eta$ ) and to

<sup>1</sup> *J. Amer. Chem. Soc.*, 1933, **55**, 476.

throw light on the precise mechanism of transport of ions ; the latter may be compared with the experimental integral heats of dilution of electrolytes.

The investigation has been carried out with these objects in view : the intention has been rather to explore the field than to work it in great detail.

### Previous Work.

Not many measurements of conductivity curves at different temperatures have been made : the earlier work was not carried to high enough dilutions for accurate extrapolation to be possible. The following comprise the more recent investigations :—

Authors.	Solvent.	Electrolytes.	Temperatures.
Walden and Ulich <sup>2</sup>	Water	Uni-univalent salts.	0°, 18°, 100°
Ekwall <sup>3</sup>	„	Substituted ammonium salts	0°, 25°, 90°
Johnston <sup>4</sup>	„	Higher valency type salts	
Walden and Ulich <sup>4</sup>	Methyl and ethyl alcohols	} Salts	0°, 25°, 56°
Walden, Ulich and Laun <sup>4</sup>			
Walden, Ulich and Busch <sup>7</sup>	Acetone	Salts	0°, 25°, 50°
Martin <sup>8</sup>	Benzonitrile	Salts	0°-70°
Philip and Oakley <sup>9</sup>	Nitromethane	Potassium Iodide	0°-85°

In all these investigations the interest is centred on the constancy or otherwise of  $\Lambda_{0\eta}$  and  $l_{0\eta}$ . Their results may be summarised : in the non-hydroxylic solvents  $\Lambda_{0\eta}$  and  $l_{0\eta}$  are constant or increase slightly with increasing temperature, but in hydroxylic solvents much larger variations occur usually in the opposite sense, *i.e.* they decrease with rise of temperature. The salts having large and comparatively unsolvated ions obey Walden's rule most closely.

### Experimental.

Measurements of electrical conductivity were made by the method of Murray-Rust and Hartley.<sup>10</sup> The constants of the cells used were determined from time to time using solutions of potassium chloride in methyl alcohol at 25° C, and were based on Fraser and Hartley's values.<sup>11</sup> The variation of cell constant with temperature is negligible.

The temperature of the water thermostat was controlled by heating lamps actuated by a toluene regulator through a relay. Cold tap water was circulated through a copper cooling coil at 15° C and ice water at 4° C at a rate sufficient to give equal periods of heating and cooling. The temperatures were checked from time to time against an NPL standard and were maintained constant within 0.01° C.

## Materials.

Methyl alcohol was prepared by the method of Hartley and Raikes,<sup>12</sup> ethyl alcohol by that of Copley, Murray-Rust and Hartley.<sup>13</sup>

Potassium chloride and iodide, lithium iodide, silver nitrate, tetraethyl ammonium perchlorate and picrate were taken from stocks of these salts purified for conductivity purposes by previous workers in this laboratory. Potassium chloride and iodide, tetraethyl ammonium picrate and perchlorate were dried to constant weight in an electric oven at 250°, 220°, 120° and 110° C. respectively; silver nitrate was dried in a small vacuum oven over phosphorus pentoxide at 80° C. Lithium iodide had been twice recrystallised from water; it was dried in the vacuum oven at 50° C. for a fortnight and the temperature then raised to 70° C. for a week without the salt becoming discoloured; the composition reached corresponded closely by analysis and in the conductivity results to  $\text{LiI} \cdot \frac{1}{2} \text{H}_2\text{O}$ . (The amount of water introduced into solution is negligible since the driest methyl alcohol obtainable contains about 0.03 per cent. of water.) B.D.H. tetraethyl ammonium bromide contained impurities after recrystallisation from ethyl alcohol; heating in a vacuum oven at 70° C. caused part of the salt to sublime, and after several weeks both analysis and the conductivity gave results agreeing with the formula  $\text{NEt}_4\text{Br}$ .

Solutions of hydrochloric acid were prepared by the method of Murray-Rust and Hartley<sup>10</sup> and used on the day of their preparation; their estimation followed the method described by Jones and Hughes.<sup>14</sup>

Solutions of potassium methoxide, ethoxide, methyl carbonate and ethyl carbonate were prepared by Jones and Hughes; the measurements on them were made in collaboration with those authors.

## Results.

(1) The results of the conductivity measurements are given in Tables I., II. and III. (Column 1: Temperature and specific conductivity of the solvent ( $k$ ). Column 2: concentration in gm. equivs./litre. Column 3: equivalent conductivity. Column 4:  $\Lambda_{\text{corr}}$ , the corrected conductivity of bases and of hydrogen chloride in ethyl alcohol.) At the foot of each run is given  $x$ , the slope of the linear part of the curve and  $\alpha$ , the Debye-Hückel-Onsager slope. In calculating  $\alpha$ , the values for the dielectric

<sup>16</sup> 32.25, the value here used for the DEC of methyl alcohol at 25° C., is probably better than the value 30.3 used in previous papers from this laboratory.

<sup>17</sup> *Phil. Mag.*, 1929, 7, 985.

<sup>18</sup> *Private Communication.*

<sup>19</sup> *J.C.S.*, 1934, 1197.

of Jones and Hughes; <sup>18</sup> no correction was applied to potassium methyl and ethyl carbonates or to hydrogen chloride in methyl alcohol for reasons given by those authors.

(3) Extrapolation of the curves was made by the method of Fuoss and Krauss,<sup>1</sup> and  $\Lambda_0$  and  $K$  (Table IV.) obtained. Where  $K$  had comparatively large values an approximation to their method was sufficiently accurate:  $\gamma$ , the degree of dissociation was obtained from

$$1 - \gamma = \frac{\Lambda_0 - \Lambda - \alpha \sqrt{c}}{\Lambda_0 - \frac{3\alpha \sqrt{c}}{2}}$$

instead of by successive approximation in

$$\Lambda = \gamma (\Lambda_0 - \alpha \sqrt{\gamma c})$$

Potassium methoxide was found to have a slope less than the theoretical so that  $\Lambda_0$  was obtained by the old method of graphical extrapolation.

(4) Values of  $\Lambda_0\eta$  and of  $\frac{\Delta\Lambda_0\eta}{\Lambda_0\eta\Delta T}$  are given in Table V. Table VI. gives approximate values of  $l_0$ ,  $l_0\eta$  and of  $\frac{\Delta l_0\eta}{l_0\eta\Delta T}$ . These have been obtained on the assumption that  $l_0\eta$  is constant with temperature for the picrate ion and by making reasonable assumptions of the temperature coefficients of  $l_0\eta$  of other ions, where necessary.

TABLE V.—VALUES OF  $\Lambda_0\eta$  AND MEAN TEMPERATURE COEFFICIENTS.

$d_1, d_2$  being the densities of the solution (assumed equal to those of the pure solvent),  $K_1, K_2$  the dissociation constants, at temperatures  $T_1, T_2$ . These values of  $Q$  must be regarded as only approximate: insufficient statistical evidence is available to establish their accuracy.

### Discussion.

#### Variation of $\Lambda_0\eta$ and $l_0\eta$ .

The present results give general confirmation to those of previous workers in showing negative temperature coefficients of  $\Lambda_0\eta$  and  $l_0\eta$  in hydroxylic solvents; the following also appear to be true.

(1) In a given solvent the values of the temperature coefficient are more negative the greater are  $\Lambda_0$  and  $l_0$ , this is illustrated graphically

FIG. 1.—Temperature coefficients of  $l_0\eta$  in water.

-- □ -- normal ions 18–100° C.

— ○ — normal ions 0–25° C.

Hydrogen and hydroxyl ions inset.

in the figure, in which values from the results of Walden and Ulich and of Ekwall in water are plotted. There is a roughly linear relationship between the temperature coefficient and  $\Lambda_0$  or  $l_0$  at a given temperature.

(2) The temperature coefficients have more negative values at lower than at higher temperatures.

(3) The temperature coefficients are on the whole increasingly negative in the order ethyl alcohol, methyl alcohol, water.

Since heats of solvation are in general positive, it does not seem possible to account for these negative temperature coefficients by an increase in ionic radius with temperature: moreover, the systematic differences between behaviours of salts in the two classes of solvents would be hard to explain on this basis, and it seems more likely that

the cause is to be found in the nature of the solvent rather than of the ions.

The experiments of Bridgman<sup>19</sup> on the effect of pressure on the viscosity of liquids showed that in this property also the behaviour of hydroxylic solvents is peculiar. They are "abnormal" since increase of pressure produces a smaller increase of their viscosity than in the case of "normal" (non-hydroxylic) liquids: it was shown that this abnormality increases in the order ethyl alcohol, methyl alcohol, water and in the case of water is less at higher than at lower temperatures. It seems likely that these two phenomena may be connected and that a pressure-viscosity effect is responsible for the negative temperature coefficients: a similar explanation of negative "B coefficients" in the viscosity equation has been suggested by Cox and Wolfenden.<sup>20</sup>

The mechanism for producing such an effect is known to exist in the electrostriction of polar solvent by ions which Zwicky<sup>21</sup> and Webb<sup>22</sup> have shown must lead to very high pressures in the immediate neighbourhood of the ions: this will lead to values of the viscosity of solvent in this region different (generally greater) from those in the bulk of the solvent. Whatever may be the actual effective values of these viscosities, Bridgman's results show that, since non-hydroxylic solvents approach the behaviour of the normal with rise of temperature, the change in these effective viscosities with temperature must be more positive in the case of hydroxylic solvents than in the case of normal solvents. The change of ionic mobility with temperature will therefore be more negative in the former than in the latter, which will account for the more negative temperature coefficients of  $A_0\eta$  and of  $l_0\eta$ . It seems reasonable to regard the zero or positive temperature coefficients found in non-hydroxylic solvents as normal, and the negative values in hydroxylic solvents as due to abnormality of the solvents presumably due to their complexity of liquid structure. It is natural that ethyl alcohol, methyl alcohol and water should be in the same order with respect to the magnitudes both of abnormality of temperature coefficients and of pressure-viscosity properties; also, since the higher the temperature the more nearly is this behaviour normal, the temperature coefficients also are more near to normal at higher than at lower temperatures.

Since the electrostriction pressure falls off very rapidly with distance from the centre of the ion, the abnormality should be most marked for the smallest and least for the largest ions: if  $A_0$  or  $l_0$  may be taken as an index of ionic size, this is found to be so.

The work of Bridgman, Zwicky and Webb shows that the viscosity should increase rapidly to very large values at a distance of 1 to 2 Å from the ion centre. The solvent immediately surrounding a very small ion is thus so viscous that it can crudely be regarded as moving entirely with the ion: it is not therefore surprising that the smallest (most mobile) ions have much the same mobilities in any given solvent.

To summarise, this very crude and imperfect picture, taking only electrostriction into account and treating the solvent as a continuum, gives a qualitative explanation of a number of facts.

<sup>20</sup> *Proc. Roy. Soc., A*, 1934, 145, 475.

<sup>21</sup> *Physikal. Z.*, 1926, 27, 271.

<sup>22</sup> *J. Amer. Chem. Soc.*, 1926, 48, 2589.

**Abnormal Mobilities.**

The ions of hydrogen in water and the alcohols and the hydroxyl ion in water have been regarded as having abnormally high mobilities; two essentially similar theories<sup>23</sup> have been put forward to account for this, both predicting the possibility of abnormal mobility wherever the ion in question can be derived from the solvent. Two criteria of abnormal mobility exist:

(1) Abnormally low temperature coefficients of mobility, predicted by both theories: these are evident in the case of the hydrogen ion in water and methyl alcohol (but not in ethyl alcohol) and of the hydroxyl ion (but not of the methoxide and ethoxide ions).

(2) The effect of small additions of water to alcoholic solutions,<sup>24</sup> producing large decreases of conductivity: this shows abnormal mobility of hydrogen ions in methyl and ethyl alcohols, but not of methoxide or ethoxide ions.<sup>25</sup>

It appears from the present results that in the case of salts the temperature coefficients of  $A_{0\eta}$  and  $l_{0\eta}$  are related to  $A_0$  or  $l_0$ ; in every proved example of abnormal mobility the points of the temperature coefficients against  $A_0$  or  $l_0$ , when plotted, lie well off any line which can be drawn through the points for salts to describe this relation. The same is true for methoxide and ethoxide and suggests that a part of the mobility of these ions also is abnormal.

**Heats of Dissociation and Dissociation Constants.**

The heats of dissociation of salts having metallic kations are large and positive, those of tetra ethyl ammonium salts small and, in the case

TABLE VIII.—NEAREST DISTANCES OF APPROACH.

of the bromide, negative. These results are in qualitative agreement with those of Jackson, Smith, Gatty and Wolfenden,<sup>26</sup> who found that the differences between the observed and calculated integral heats of dilution in methyl alcohol, were large and positive for metallic salts, but small and negative for tetra ethyl ammonium bromide. These differences may in part re-

present the heats of dissociation involved in diluting solutions of incompletely dissociated electrolytes.

<sup>23</sup> Hückel, *Z. Elektrochem.*, 1928, **34**, 546; Bernal and Fowler, *J. Chem. Physics*, 1933, **1**, 515.

<sup>24</sup> Hughes and Hartley, *Phil. Mag.*, 1933, **15**, 610.

<sup>25</sup> Jones and Hughes, *J.C.S.*, 1934, 1197.

<sup>26</sup> *J.C.S.*, 1934, 1376.

The apparently deciding rôle of kations in determining the heat of dissociation is probably connected with their power of solvation, since dissociation of a molecule or ion pair must lead to increased solvation and metallic ions are known to be generally more highly solvated than tetra ethyl ammonium.

The dissociation constants of the salts are roughly in inverse order of their conductivities in accordance with the ion pair theory. The sums of radii of the ions of these salts have been calculated from  $\Lambda_0$  by Stokes' Law and from  $K$  using the method of Fuoss and Krauss.<sup>17</sup> (Table VIII.). Reasons have been given for supposing the values by the former method to be unreliable: those obtained by the latter method are at best only approximate.

### Summary.

(1) The electrical conductivities of solutions in methyl alcohol of potassium chloride, silver nitrate, potassium methyl carbonate, tetra ethyl ammonium perchlorate, tetra ethyl ammonium picrate, tetra ethyl ammonium bromide, potassium methoxide and hydrogen chloride: in ethyl alcohol of potassium iodide, lithium iodide, potassium ethyl carbonate, tetra ethyl ammonium perchlorate, tetra ethyl ammonium picrate, potassium ethoxide and hydrogen chloride have been measured at 25°, 15° and 4° C.

(2) By the method of Fuoss and Krauss, the limiting conductivities and dissociation constants have been obtained.

(3) The negative temperature coefficients of  $\Lambda_0$  and  $l_0$  in hydroxylic solvents have been explained on the basis of the effect of electrostriction pressure on the local viscosity in the neighbourhood of ions.

(4) It is suggested that the methoxide and ethoxide ions exhibit abnormal mobility.

(5) Heats of dissociation have been calculated and compared with values of the integral heats of dilution of electrolytes in methyl alcohol.

The author expresses his gratitude to Sir Harold Hartley (in whose laboratory this work was done) for advice and encouragement, and to Messrs. O. L. Hughes and G. E. M. Jones for experimental assistance.

## CHEMICAL REACTION IN ELECTRIC DISCHARGES. PART II. THE CHEMICAL ACTIVITY OF IONS.

BY R. WINSTANLEY LUNT.

*Received 11th September, 1936.*

The view that chemical reaction in the electric discharge is conditioned by the chemical activity of atomic, or molecular, charged particles has been based mainly on three groups of experimental data: (1) the similarity between reaction caused by an electric discharge and

that initiated by  $\alpha$ -particles,<sup>1</sup> and the proportionality, in the latter case, between the amount of chemical change and of ionisation (constancy of the M/N ratio),<sup>2</sup> (2) the correspondence in electron beam experiments between the critical energy for chemical change and that for the onset of ionisation, and (3) the general character of discharge reaction and the proportionality between the current carried in a glow discharge and the rate of chemical reaction in it.<sup>3, 4, 5, 6</sup>

The aim of this paper is to review the subject in the light of the statistical theory of Part I.; for whilst certain optically allowed transitions lead to ionisation, and, as effected by electron impact, might therefore account, in some cases at least, for (3) above, there are a number of cases in which it appears more probable that discharge reaction is attributable mainly to the uncharged products of collisions between electrons and the reactant molecules.

### 1. The Data for Reaction Initiated by $\alpha$ -Particles.

The facts stated in (1) above would lead to the conclusion that ions are responsible for the observed reaction were it not known, as pointed out by Rutherford, Chadwick and Ellis,<sup>7</sup> that, in molecular gases, less than half the energy of  $\alpha$ -particles is used in effecting ionisation. Evidence for the occurrence of excitation along  $\alpha$ -particle tracks has long been available<sup>8, 9</sup>. Since it is known from photo-chemical experiments that excitation processes frequently lead to products which initiate reaction, it may not be necessary to look further than these for an explanation of  $\alpha$ -particle reaction, as Emeléus and Lunt,<sup>10</sup> and more recently, Eyring, Hirschfelder and Taylor<sup>11</sup> have surmised.

### 2. The Data of Electron Beam Experiments.

The technique of electron beam experiments to determine the least electron energy for which reaction occurs is essentially the same as that for determining the critical energy for excitation and ionisation.<sup>12</sup> But the chemical experiments are beset with considerable additional difficulties which arise from the comparative insensitivity of chemical,

compared with physical, methods for the detection of the onset of the formation of a new molecular or atomic species in the gas.

At the time when the critical energies for reaction were determined it was found in some systems that this critical energy was identical with the then accepted value of the critical energy for the ionisation of one of the reactants; such identity led naturally to the conclusion that the reaction was initiated by the ions formed at this critical energy. This identity no longer holds for the more recent and precise determinations of the critical energy for ionisation. Thus, for example, the values attributed to the critical energy for reaction in mixtures of (a) hydrogen and nitrogen,<sup>13</sup> (b) hydrogen and carbon monoxide,<sup>14</sup> and (c) nitrogen and oxygen,<sup>15</sup> are, in each case, at least 1 el.-v. *above* the accepted critical energies<sup>16, 16(a)</sup> for the simple ionisation of the reactants. In these cases, it is clear that the presence of the ions of both components is inadequate to initiate reaction. In other cases, for example, in hydrogen<sup>17</sup> and in oxygen<sup>18</sup> the values found for the critical energy for reaction, or chemical change, is definitely lower than that for simple ionisation,<sup>16</sup> and may be identified with a critical energy for excitation as determined, for example, from spectroscopic data.<sup>16(a), 19</sup> There is thus no evidence from electron beam experiments for the initiation of chemical change by ions; on the other hand they afford definite evidence that the products of excitation processes cause reaction.

### 3. The Data for Discharge Reaction.

Since Brewer<sup>5</sup> has contributed the widest array of data for reaction in the glow discharge, and has been a most emphatic supporter of the ion reaction mechanism hypothesis, his views will be discussed here although similar conclusions have been reached by others.

An explanation has been sought for the constancy of the current efficiency in the negative glow,  $\beta_p$ ,  $\alpha$ , by considering the ionisation produced in the negative zones as equivalent to that produced by a flow of electrons, numerically equal to the current carried by the discharge, and having initial energy given by the cathode fall in potential. Linder's<sup>20</sup> more precise analysis of the régime in the negative zones, later amplified by Emeléus and Kennedy,<sup>21</sup> shows that Brewer's model of the negative zones is too incomplete to warrant further discussion.

Both excited atoms and molecules have been excluded from possible reaction mechanisms because the intensity of light emitted by them in a glow discharge, considered as a function of pressure, is apparently unconnected with the rate of chemical reaction; this is to be expected because, for normal excited states, having a life-time of  $10^{-9}$  —  $10^{-7}$  sec.

radiation will occur before collision for the pressure range in Brewer's experiments. But, of course, this consideration does not exclude unexcited atoms, or metastable atoms and molecules, all of which may be the products of excitation processes.

Atoms, or other fragments, resulting from the dissociation of electronically excited molecules have also been excluded because there is no maximum in the reaction rate corresponding to the conditions in which atoms or fragments may most easily be extracted from a discharge. The equilibrium concentration of atoms, or other fragments, is, however, determined by the rate of their production and the rate of their destruction by chemical reaction, including the reformation of the molecules from which they were formed; hence, in the absence of auxiliary data, no simple relation is predictable between the stationary concentration of such fragments and the rate of formation of the final product of a discharge reaction.

The exclusion of the above mentioned uncharged products of electron collision with reactant molecules, which is now seen to be almost certainly unwarranted, led naturally to the view that the explanation for the observed reaction must be sought in terms of the charged products of such collisions. In further support of this conclusion, Brewer called attention to the sharply defined bands of reaction product that are observed on those portions of the walls of the reaction vessel, when suitable refrigerated, that enclose the regions of most intense ionisation, the positive column and of the negative glow;<sup>20</sup> these regions, are, however, also those in which the concentrations of excited atoms and molecules are greatest.<sup>20</sup> Similar deposits have been observed by Banerji and Ganguli<sup>21</sup> whose work appears to show that they arise from the neutralisation of the random positive ion current at the walls. Furthermore, the existence of the so-called "ion-exchange" reactions of Kallmann and Rosen<sup>22</sup> at once affords a possible explanation of these phenomena because, in many cases, the ionisation potential of the "product" molecules is lower than that of any of the reactants, and the pressure is so high that a "product" molecule produced in the gas phase could make a number of collisions with ions of the reactant molecules before reaching the walls.

Brewer has also supposed that the ions of the reactant molecules may initiate reaction when they reach the walls, the energy of ion recombination being available for dissociating either the recombined ion or some neighbouring molecules, or for providing part of the activation energy in reactions involving the neutralised ion. Apart from the lack of direct evidence for such processes, discussed in § 4, it appears likely that even if wall (or other surface) recombination were followed by dissociation, the resulting fragments, if atomic, would be preferentially adsorbed, and subsequently recombine with like fragments reforming the molecules from which they were produced; a considerable part of the energy released in the ion recombination would thus appear finally as heat conveyed to the walls, which the view generally accepted.<sup>24</sup> It is interesting to note that, for the formation of ammonia from nitrogen-hydrogen mixtures, Brewer himself reported data<sup>5</sup> for the dependence of the rate of synthesis on the relative area of the anode and cathode, and which affords a strong indication that the ions reaching the cathode,

<sup>22</sup> See, for example, Compton and Langmuir, *ibid.*, 1930, 2, 191.

and recombining there, do not contribute appreciably to the observed reaction.

There is thus no evidence from the data for discharge reaction that charged particles are essential to the initiation, or to any other step, of the mechanism by which reaction occurs.

#### 4. The Reactivity of Ions.

There are two main ways in which it has been supposed that charged molecular or atomic particles can cause chemical reaction: firstly, the energy liberated in the recombination of a positive ion with an electron, or negative ion, may be available to dissociate or activate the recombined ion, or some other particle with which it is in collision during the recombination process; secondly, an ion may have a specific chemical reactivity analogous to that of neutral molecules, atoms, and free radicals.

##### 4.1. The Energy Liberated in Ion Recombination.

Since the disposal of this energy at the surface of a discharge tube has already been discussed, it remains to consider processes occurring in the gas phase. For simplicity the argument will be restricted to diatomic molecules and molecular ions, although it will be seen that it can readily be extended to more complicated cases.

In the recombination of an electron with a diatomic ion  $AB^+$  (where A may be identical with B), the condition for the formation of a stable molecule, AB, is that energy equal to the sum of the energy of ionisation of AB,  $I_0$ , and the kinetic energy of the electron,  $I_k$  must be radiated (or transferred to a third body) in the life-period of the ion-electron collision complex. This life-period may be roughly estimated as the time an electron spends in crossing a molecular diameter,  $10^{-8}$  cm.; for an electron of velocity about  $10^7$  cms. sec.<sup>-1</sup>, or of energy about 0.04 el.-v., this time is about  $10^{-15}$  sec., and would be correspondingly smaller for electrons of greater energy. Since no selection rules are contravened in the radiative process, the transition probability (the Einstein " $A$ " coefficient) may be taken to be that of a normal allowed transition, about  $10^8$  sec.<sup>-1</sup>; it follows that the probability of stable molecule formation is of the order of  $10^{-15} \times 10^8 = 10^{-7}$  in a single collision. Whilst no recombination spectra are known for molecules, the values of this probability for atoms, deduced from the absolute intensity of the recombination spectra,<sup>24</sup> confirms the above rough estimate, and establishes that gas phase recombination by the emission of radiation is an extremely rare process, a conclusion in agreement with that reached from purely electrical considerations.<sup>24</sup> In molecular ions there is, however, the additional possibility that the energy released in recombination might be transferred to the internal motions of the molecule in the ground state and thus cause dissociation, or at least considerable activation. Such a process would be equivalent to the transfer of electron kinetic energy to molecular vibration (and rotation), processes known to be of low probability both from experiment,<sup>25</sup> and from theoretical considerations.<sup>26</sup> Thus, whilst the available energy

<sup>24</sup> Bailey and others, *Phil. Mag.*, 1923, **46**, 213; 1925, **50**, 825; 1928, **6**, 1073; 1930, **10**, 145; 1932, **13**, 993; Harries, *Z. Physik*, 1927, **42**, 26; Rammen, *ibid.*, 1931, **70**, 353.

<sup>25</sup> Mott and Massey, *The Theory of Atomic Collisions*, Oxford, 1933, 217; Bloch and Bradbury, *Physic. Rev.*, 1935, **48**, 689.

would be more than sufficient to cause dissociation in many cases, the low probability limits such decomposition to the class of very infrequent processes.

We now consider the case where the energy of (molecular) ion recombination is available for production of an excited molecular state of the recombined ion, a particular case arising when the transition occurs at such an internuclear distance that dissociation follows. The argument here follows that of Massey and Smith<sup>27</sup> for dissociation consequent upon electron attachment: if we consider, as before, a collision between an electron of energy  $V_k$  and an ion  $AB^+$  in its lowest vibrational state,\* it can at once be seen that the collision complex is indistinguishable from the neutral molecule  $AB$  in which the internuclear distance, by the Franck-Condon principle, is the equilibrium internuclear distance of the ion  $AB^+$  (which we shall denote by  $r_+$ ), and containing energy  $V_i + V_k$ . If now there happens to be an excited state of  $AB$  such that at the internuclear distance  $r_+$ , its energy, relative to the ground state, is nearly† equal to  $V_i + V_k$ , the systems will be in resonance and transitions to the excited state of  $AB$  will occur. But, even if there happens to be a suitable excited state, the systems will be in resonance only for electrons having energy very close to  $V_k$ ; it has been seen in Part I. that in the negative glow and the positive column the electrons have an energy distribution, and therefore but a very small fraction of the total electrons present may have energy close to  $V_k$ , with the result that in either of these discharge zones the process may be a very infrequent one. The simplest variant of this process is that a third molecule,  $CD$ , is present during the collision and that this molecule is activated or dissociated by absorbing the energy liberated in the recombination of the ion. In this case, too, the probability of energy transfer would be appreciable only if there were a level in  $CD$  in resonance with the available energy,  $V_i + V_k$ . The infrequency of ternary collisions at the low pressures used in most discharges, the low relative concentrations of ions and electrons,<sup>28</sup> and the possibility that only a small fraction of the electrons have energy close<sup>29</sup> to  $V_k$ , are three factors all tending to restrict such collisions (even if every one of these leads to activation or dissociation) to the class of very infrequent processes, considerably inferior in rate to the observed rates of chemical reaction in discharges.

The next type of process to be considered is that in which an ion,  $AB^+$ , captures an electron from another molecule  $CD$  in a collision; the energy liberated is then the difference between the ionisation energy of  $AB$  and that of  $CD$ , a quantity which will be denoted by  $V_0$ . By the Franck-Condon principle, if such an electron transfer occurs the resulting new ion,  $CD^+$ , would be produced at the internuclear distance of the neutral molecule  $CD$ ,  $r_0''$ ; the process will occur with appreciable probability only if there happens to be an excited state of  $CD^+$  such that at the internuclear distance  $r_0''$  its energy relative to that of the normal state

<sup>27</sup> Massey and Smith, *Proc. Roy. Soc., A*, 1936, 155, 472.

\* The lowest vibrational state is considered because, in most of the discharge conditions of present interest, the majority of ions are probably in this state; the argument is, however, easily extended to higher vibrational states.

† The order of the energy discrepancy will be 1 e.v. since this must be same as that due to the change of internuclear distance in a transition between different electronic states.<sup>31</sup>

<sup>28</sup> Stueckelberg, *Physic. Rev.*, 1932, 42, 518.

<sup>29</sup> Darrow, *Electrical Phenomena in Gases*, Baltimore, 1932.

of  $CD^+$  is nearly \* equal to  $V_d$ , for then the systems will be in resonance. The best known example of such an ion reaction is afforded by the work of Smyth and Stueckelberg<sup>30</sup> on collisions between  $Ne^+$  ions and normal oxygen molecules. In this case it happens that the energy acquired by the excited ion,  $O_2^+$ , is greater than the dissociation energy, and it therefore dissociates spontaneously into O and  $O^+$ . Apart from the restriction implicit in the necessity for there being an excited state of  $CD^+$  in resonance with  $V_d$ , the low pressures and low concentrations of ions in most discharges of present interest limit the maximum possible rates of such processes to comparatively low values.

The last type of collision process we consider is that between a positive ion and a negative ion: this is most simply treated as a variant of the previous case in which the collision complex of  $CD^-$  and  $AB^+$  may be regarded, after electron transfer has occurred, as composed of AB and CD in which the internuclear distances are, respectively, the equilibrium internuclear distances of the ions from which they are derived; the complex as a whole then contains the energy  $V_d' = V_i - V_{d,-}$ , where  $V_i$  has the same significance as in the previous cases, and  $V_{d,-}$  denotes the ionisation energy of  $CD^-$ . The reaction which will then occur is that for which the sum of the energies of the excited states of CD and AB is most closely in resonance with the available energy,  $V_d'$ ; in general this will occur with CD in an excited vibrational level of the ground electronic state, and with AB in some vibrationally excited upper electronic state. Furthermore, since  $V_{d,-}$  is likely to be small † compared with  $V_i$ , and since there are numerous upper electronic states with energies lying close to  $V_i$  (in any molecule), it is probable that the excited states necessary for resonance with  $V_d'$  exist in most cases; the electronically excited state of AB must then, if it is stable, lose its energy by radiation, or, if unstable, dissociate. Whilst the rate of recombination of ions of opposite sign has been the subject of many investigations, no observation of the radiation consequent on this has been reported. The observed rate of recombination is remarkably high, being at atmospheric pressure approximately  $10^4$  that of the bi-molecular collision rate of the corresponding neutral particles: recombination may therefore be of importance in connection with chemical reaction in discharges because, as seen above, the energy liberated may cause dissociation, or lead to the emission of radiation which might be absorbed by the other molecules present. On the other hand, there are few discharges of present interest for which there is evidence of the existence of negative ions in concentrations exceeding a very small fraction of that of the positive ions.

Summarising this discussion, it is seen that in all cases the likelihood of processes occurring in which the energy of recombination may become available for chemical reaction depends on the existence of excited states of ions and of neutral molecules satisfying certain particular energy requirements. Any particular case must therefore be considered on its merits, but in the present somewhat scanty state of

\* That is, within about 1 e.v.

<sup>30</sup> Stueckelberg and Smyth, *Physic. Rev.*, 1928, **32**, 779; Stueckelberg, *ibid.*, 1929, **34**, 65.

† For example, the energy of electron attachment to an oxygen molecule<sup>31</sup> is about 0.1 e.v.; the energy of detachment is probably of the same order of magnitude.

<sup>31</sup> Loeb, *Physic. Rev.*, 1933, **43**, 6.

our knowledge of the higher electronically excited states of molecules, it is only in a few cases that the problem can be adequately discussed. Apart from this restriction, in the case of ion-electron collisions, there is also a restriction to a very narrow range of electron energies. The two remaining processes either require ternary collisions, or involve a particle of a type which exists in most discharges of interest at relatively low concentrations only. It is therefore reasonable to suppose that in most discharge reactions none of these processes is operative unless there is special evidence to the contrary.

#### 4.2. The "Chemical" Reactivity of Ions.

Although it has been frequently postulated that chemical rearrangement may take place as a result of collisions between charged and uncharged molecules, there is only one known case of charged particles effecting reaction when these have kinetic energy of the same low order as is possessed by molecular ions in discharges in which chemical reaction has been examined. This is the reaction  $H_2 + H_3^+ = H_3^+ + H$ , the occurrence of which was established by Dorsch and Kallmann;<sup>32</sup> the fact that detectable amounts of atomic hydrogen were formed, despite the small concentrations of  $H_3^+$  ions present, suggests that the energy of activation is small and the velocity constant large, in agreement with calculations based on wave mechanical theory.<sup>33, 11</sup>

Direct investigation by the use of ion beams is beset with difficulties similar to those encountered in working with electron beams (see § 2); whilst there are considerable discrepancies between the results of different investigators,<sup>10(a)</sup> it is clear that the critical energy for reaction as effected by ion beams is at least about 20-30 e.v., and thus vastly in excess of the mean energy of ions in many discharges<sup>30</sup> causing chemical reaction. Even larger values of critical (ion) energy are found for electronic excitation by ion beams,<sup>34</sup> and wave mechanical theory predicts that no appreciable excitation will occur until the ion energy is considerably in excess of that necessary to effect the excitation process itself.<sup>35</sup>

It is true that the rate at which ions collide with neutral reactant molecules to give chemically new products may be discussed in terms of expression (3), Part I, when  $n_+$  is replaced by the ion concentration,  $n_+$ , when  $V$  denotes the kinetic energy of a colliding ion,  $Q(V)$  the probability cross-section (in units of  $\pi a_0^2$ ) for a specified collision process,  $f(V)$  the energy distribution function for the ions, and when  $k$  is replaced by  $4.37 \times 10^8 \times a$ , where  $a$  is the ratio of the mass of the ion to that of a hydrogen atom. But since the current carried by a discharge cannot usually be expressed in terms of the drift velocity of the ions, it is usually not possible to derive from this modified form of expression (3) expressions for the current and energy efficiencies of such ion collisions which have properties similar to those of the corresponding quantities as observed for reaction in discharges. This result is not in itself sufficient to exclude the possibility that ions initiate reaction in discharges; but since  $f(V)$  is appreciable only for  $V$  less than 1 e.v., in the

<sup>32</sup> Dorsch and Kallmann, *Z. Physik*, 1925, 28, 452.

<sup>33</sup> Coulson, *Proc. Camb. Phil. Soc.*, 1935, 31, 244; Eyring, Rosen and Hirschfelder, *J. Chem. Physics*, 1936, 4, 121.

<sup>34</sup> Kirschstein, *Z. Physik*, 1930, 60, 184; Appleyard, *Proc. Roy. Soc., A*, 1930, 128, 330.

positive column and the negative glow,<sup>20</sup> and if, as seems likely<sup>10(a), 24</sup> from experiment,  $Q(V)$  is zero for  $V$  less than about 20 e.v., it follows that the overlap between  $Q(V)$  and  $f(V)$  and, hence, the rate of collision, must be extremely small. By evaluating the integral in this modified expression (3) for any likely values of  $Q(V)$  and  $f(V)$ , it is easy to show that the resulting value for the rate is, by many powers of ten, inferior to the rate of reaction frequently observed in discharge reaction. In such cases it would be necessary to suppose that each ion-reactant collision ultimately gives rise to the formation of a correspondingly large number of molecules of the final product; in most cases such a possibility, is, of course, excluded.

Concerning the activation energy of collisions leading to chemical rearrangement between molecular ions and molecules having comparable kinetic energy very little is known. There is no reason to suppose from the scattering of molecular ion beams in molecular gases that the rate of transfer of kinetic into vibrational energy is significantly different from that of the corresponding neutral particles. By neglecting the effects arising from the charges on the particles, estimates of the activation energy may be derived by considering the heats of dissociation, equilibrium internuclear distances, and molecular diameters, of the colliding particles according to the method discussed by Franck and Rabinowitch;<sup>25</sup> this procedure leads obviously to activation energies of the same order as those for thermal reaction between neutral molecules, 1.5-2.5 electron-volts. In one case only, the reaction  $H_3^+ + H_2 = H_3 + H$ , has the problem been approached from wave mechanical theory:<sup>26, 27</sup> Eyring concludes<sup>28</sup> that the activation energy is small, but although this result conflicts with the prediction from the Franck-Rabinowitch rule, no general conclusion can be drawn from this single application of wave mechanical theory.

Summarising this discussion of ion reactivity, firstly, it must be emphasised that there is only one example known for which there is direct evidence, and this is purely qualitative. Secondly, whilst in this one case (for which alone the necessary calculations have been performed) the wave mechanical analysis of the problem predicts a low activation energy, there is no indication from scattering experiments that the same may be true for other (postulated) cases; moreover, by analogy with thermal reactions between neutral particles, it may be anticipated that the activation energy will not be very small. Thirdly, the absence of fast moving ions in discharges excludes the possibility that electronic excitation by ions occurs in these. Whilst it is necessary to consider any particular case on its merits, it is thus seen to be improbable that any reaction in a discharge at temperatures not greatly exceeding 300° K. can be attributed to the chemical reactivity of the ions present.

## 5. Conclusions and Summary.

The following conclusions are reached from the preceding discussion of the various aspects of the hypothesis that the chemical reactions occurring when a discharge passes through a gas are attributable to the ions present. *Firstly*, the analogies presented by reactions due to  $\alpha$ -particles do not support this hypothesis since they themselves are probably due to the excitation caused by the  $\alpha$ -particles. *Secondly*, the data for critical potentials for electron beams indicate that these

<sup>25</sup> Franck and Rabinowitch, *Z. Elektrochem.*, 1930, 36, 794.

are below the ionisation potentials of the reactant molecules. *Thirdly*, the arguments which have been advanced from the general character of discharge reactions have been shown to be inconclusive. *Fourthly*, collision processes in which the energy of ion recombination may become available for initiating reaction have been shown to belong to a class of infrequent events for the conditions obtaining in glow discharges; a possible exception is the case of recombination between ions of opposite sign, but there is little evidence for the existence of negative molecular ions in significant concentration in many discharges in which chemical reaction has been studied. *Lastly*, there is only one example known for which there is direct evidence of the chemical reactivity of an ion of low kinetic energy; there is no evidence from scattering experiments for many of the other cases which have been postulated.

Thus, whilst no categorical statement is possible, and indeed any particular case must be considered on its merits, there are seen to be many reasons for believing that chemical reaction in discharges is unlikely to be attributable to the ions there present.

To Dr. H. S. W. Massey the author wishes to express his deep indebtedness for many suggestions, and for the numerous opportunities afforded him for discussing the problems raised in this paper, particularly those in Section 4.

## THE RAMAN SPECTRUM OF DEUTERO-SULPHURIC ACID.

BY ALAN H. LECKIE.

*Received 16th September, 1936.*

The Raman spectrum of sulphuric acid has been very thoroughly investigated,<sup>1</sup> and the lines in the spectra of the pure acid and its solutions in water have been simply explained on the basis of successive dissociation of the  $\text{SO}_3(\text{OH})_2$  molecule into  $\text{H}^+$ ,  $\text{HSO}_4^-$ , and  $\text{SO}_4^{2-}$  ions. There is, however, a definite shift in many of the lines on dilution of the acid, and this shift is too large to be entirely explained by assuming that it is due to changes in intermolecular forces. Woodward and Horner<sup>2</sup> from a careful study of microphotometer curves suggest that the broad lines whose frequencies vary can be analysed into narrow components of constant frequency, characteristic of the different molecular or ionic species present. Rao<sup>3</sup> had also put forward a similar suggestion, comparing the spectra of pure  $\text{H}_2\text{SO}_4$  and  $\text{KHSO}_4$ . On the other hand Bell and Jeppesen,<sup>4</sup> after experiments performed over a very wide range of dilutions, could find no trace of separate

<sup>1</sup> For references see Angus and Leckie, *Proc. Roy. Soc., A*, 1935, 149, 327.

<sup>2</sup> *Proc. Roy. Soc., A*, 1934, 144, 129.

<sup>3</sup> *Ind. J. Physics*, 1933, 8, 123.

<sup>4</sup> *J. Chem. Physics*, 1935, 3, 245.

components on their microphotometer curves, and obtained evidence for a gradual shift.

The chief difficulty is that the breadth of the  $\text{H}_2\text{SO}_4$  lines, and the presence of a relatively strong continuous background in the spectrum, renders the usual analysis by microphotometer curves taken under high dispersion of little value. If, however, the hydrogen in sulphuric acid is replaced by deuterium, the lines due to  $\text{SO}_2(\text{OH})_2$  should show a definite isotope shift, those due to the  $\text{HSO}_4^-$  ion a smaller shift, whilst those due to the  $\text{SO}_4^{--}$  ion should be unaltered in frequency. Then, if the dilution shifts are due to the changing intensity of different components of the broad lines of the Raman spectrum, they should be appreciably different in  $\text{H}_2\text{SO}_4$  and  $\text{D}_2\text{SO}_4$ .

The spectrum of  $\text{D}_2\text{SO}_4$  is also of interest in connection with the general isotope effect in spectra. Deuterium substitution in acetic acid has been studied by Angus, Leckie, and Wilson<sup>5</sup> and Engler,<sup>6</sup> and the frequencies of the lines in the spectrum of  $\text{CH}_3\text{COOD}$  are in many cases intermediate in numerical value between the corresponding values in  $\text{CH}_3\text{COOH}$  and  $\text{CD}_3\text{COOD}$ . This is particularly marked in the lower frequencies which almost certainly arise in parts of the molecule well removed from the point of substitution, and in which one would expect almost the same value in  $\text{CH}_3\text{COOH}$  and  $\text{CH}_3\text{COOD}$ . This result was kept in mind during the examination of  $\text{D}_2\text{SO}_4$ , but the isotope shift in this substance is much smaller, and of the expected order.

### Experimental.

The  $\text{D}_2\text{SO}_4$  was prepared by the interaction of  $\text{SO}_2$  and 99.6 per cent.  $\text{D}_2\text{O}$ . The small amount of residual protium present cannot have any appreciable effect on the Raman spectrum.  $\text{SO}_2$  was distilled *in vacuo* from oleum into a glass vessel until a known weight of pure  $\text{SO}_2$  was obtained. This  $\text{SO}_2$  was distilled directly into the theoretical weight of  $\text{D}_2\text{O}$  so as to produce 100 per cent  $\text{D}_2\text{SO}_4$ ; the reaction proceeded smoothly at  $0^\circ\text{C}$ . In preliminary runs it was found that a very small quantity of residue, which could not be distilled over, remained in the  $\text{SO}_2$  vessel after the distillation; allowance was made for this in weighing the theoretically equivalent quantities.

The Raman spectra were obtained with the apparatus previously employed,<sup>4</sup> using a dispersion of 20 Å/mm. at 4600 Å. 1.6 c.c. of 100 per cent.  $\text{D}_2\text{SO}_4$  was placed in the Raman tube and its spectrum obtained.  $\text{D}_2\text{O}$  was added in stages to obtain the spectra of the acid at different concentrations. These concentrations, calculated from the amount of  $\text{D}_2\text{O}$  added, were not known to more than about 5 per cent. accuracy, but as the spectrum was not sensitive to such a concentration change it was considered unnecessary to make an accurate analysis at each dilution. Exposures of from 6 to 70 hours were given. For most of the plates the 4047 Å line was filtered out with sodium nitrite solution, some, however, were taken with unfiltered light, or with the 4047 Å line using an iodine filter. A fairly strong continuous background was present in all the spectra, and most of the Raman lines were rather diffuse. By taking the mean of from 5 to 10 sets of lines for each strength of acid the frequencies of most were obtained to within an error of  $\pm 3\text{ cm.}^{-1}$ , but for the weakest lines the error is about  $\pm 10\text{ cm.}^{-1}$ . The approximate intensity of each line is denoted as (s)-strong, (m)-medium and (f)-faint.

<sup>5</sup> *Proc. Roy. Soc., A*, 1936, 155, 183.

<sup>6</sup> *Z. physik. Chem., B*, 1936, 32, 471.

## Results.

In Table I. the frequencies (in  $\text{cm.}^{-1}$ ) of the Raman lines of  $\text{D}_2\text{SO}_4$  are compared directly with the corresponding values for  $\text{H}_2\text{SO}_4$  obtained by previous investigators.

In  $\text{D}_2\text{SO}_4$  line (a) was weaker than the corresponding line in  $\text{H}_2\text{SO}_4$ , and could not be resolved. Also, the absence of line (e) in the spectrum of the "heavy" acid is not significant, as in  $\text{H}_2\text{SO}_4$  it is faint and not universally reported, although it has certainly real existence. The presence of line (f) in the 100 per cent.  $\text{D}_2\text{SO}_4$  spectrum shows that a trace of  $\text{D}_2\text{O}$  was present. A very small amount of water suffices to make this line very strong in the spectrum of  $\text{H}_2\text{SO}_4$ , so its appearance here is clearly due to difficulty in distilling exactly equivalent quantities of  $\text{D}_2\text{O}$  and  $\text{SO}_3$  in the preparation. Lines (g), (h), and (i) were very faint and difficult to measure accurately. Most authors on  $\text{H}_2\text{SO}_4$  quote (g) and (h) together as a fairly strong, single line, but there is considerable discrepancy in the published

values, and the presence of two lines in  $\text{D}_2\text{SO}_4$  indicates that Woodward and Horner, and Bell and Jeppesen are correct in reporting two lines here. The only lines showing a definite isotope shift are (b), (c), and (d); these shifts are discussed later. The apparent shifts in (g), (h), and (i) are all within experimental error.

Table II. gives the values found for  $\text{D}_2\text{SO}_4$  at different concentrations in  $\text{D}_2\text{O}$ , and the corresponding figures for  $\text{H}_2\text{SO}_4$ . Considering the number

of investigations that has been made on  $\text{H}_2\text{SO}_4$ , the agreement between published results is not good, and in Tables I. and II. the most probable values, obtained by comparing as far as possible all the data available, are given.

It is clear that the  $\text{D}_2\text{SO}_4$  spectra show a dilution shift in exactly the same manner as  $\text{H}_2\text{SO}_4$ . It is rather surprising that the bisulphate ion frequency ( $f$ ) (about  $1050\text{ cm}^{-1}$ ) does not show any isotope effect—the values in the "heavy" acid are, in fact, slightly higher—and this anomaly will be discussed later. The general isotope effect is, as might be expected, quite small. As dilution progressed the  $\text{D}_2\text{O}$  band, centred at about  $2510\text{ cm}^{-1}$ , appeared and became well defined at dilutions above 50 per cent., this corresponds to the behaviour of the water band in sulphuric acid.

### Discussion.

The effect of successive dissociation of the sulphuric acid molecule into bisulphate and sulphate ions was evident in the earliest Raman investigations on this substance, and is the most prominent feature of the spectrum. In addition there are two points of interest—the dilution shift, and the effect of hydration of the acid on the spectrum. The explanation of the dilution shift advanced by Woodward and Horner covers the observed facts in a very satisfactory manner, yet since Bell and Jeppesen, from their extensive investigation, suggest that there is no evidence for the composite character of many of the lines the results from  $\text{D}_2\text{SO}_4$  must be taken into consideration. Recently, also, Cartwright, in a study of the far infra-red spectrum <sup>7</sup> of  $\text{H}_2\text{SO}_4$ , and Plyler and Williams, investigating the infra-red spectrum of heavy acid solutions, <sup>8</sup> have drawn attention to the probable association of the acid molecules with water. Cartwright suggests that the effect of adding water to sulphuric acid is first, the formation of some hydrated sulphuric acid  $(\text{SO}_4)^{--}(\text{OH})_4^{++}$ , then the formation of a hydrated bisulphate ion  $(\text{H}_2\text{SO}_4)^-$ , and finally sulphate ions  $(\text{SO}_4)^{--}$ ; suggestions which must be kept in mind in a discussion of the Raman spectrum.

Considering the results for  $\text{D}_2\text{SO}_4$  in more detail, it is seen that frequency ( $a$ ) (about  $410\text{ cm}^{-1}$ ) increases in displacement with dilution in exactly the same way as in  $\text{H}_2\text{SO}_4$ . Woodward and Horner attribute this increase in  $\text{H}_2\text{SO}_4$  to the presence of three components, one of  $381\text{ cm}^{-1}$  due to  $\text{H}_2\text{SO}_4$ , a common frequency  $417\text{ cm}^{-1}$ , and one of  $452\text{ cm}^{-1}$  due to  $\text{SO}_4^{--}$ . On account of the faintness of the line in  $\text{D}_2\text{SO}_4$  the actual frequency of the lower component of this line could not be determined. Measuring its breadth gave the lower limit of the line as  $370\text{ cm}^{-1}$ , but this is not conclusive evidence that an isotope shift in the  $381\text{ cm}^{-1}$  component has taken place. Such a shift would have confirmed the origin of this line in the undissociated molecule. The agreement in the values for dilute  $\text{D}_2\text{SO}_4$  and  $\text{H}_2\text{SO}_4$  does seem to prove, however, that part of this line is due to the  $\text{SO}_4^{--}$  ion. The value of  $435\text{ cm}^{-1}$  in the spectra is intermediate between  $415\text{ cm}^{-1}$  (characteristic of the  $=\text{SO}_2$  group and found in chlorosulphonic acid and sulphuryl chloride) and  $455\text{ cm}^{-1}$  (characteristic of sulphates) both of which would be unaffected by deuterium substitution. Similar remarks apply to ( $b$ ) and ( $d$ ) (lines at about  $570$  and  $905\text{ cm}^{-1}$ ). Here, and particularly with ( $d$ ), there are definite isotope shifts in the concentrated acid but not in the dilute, thus affording direct

<sup>7</sup> *J. Chem. Physics*, 1936, 4, 413.

<sup>8</sup> *Ibid.*, p. 460.

evidence that these lines are composite and consist of parts attributable to separate origins in the different concentrations, one due to  $\text{H}_2\text{SO}_4$ , and the other to one of the ions.

The line (c) has not been reported in many investigations of  $\text{H}_2\text{SO}_4$ . There is a faint, but quite well-defined line at  $711\text{ cm}^{-1}$  in  $\text{D}_2\text{SO}_4$ , and it seems clear that this must correspond to the  $741\text{ cm}^{-1}$  line in  $\text{H}_2\text{SO}_4$ . Pai<sup>9</sup> regards this line as characteristic of the undissociated molecule, and this assignment is probably correct since it appears only in the most concentrated acid and is appreciably shifted in  $\text{D}_2\text{SO}_4$ .

Line (e), at about  $980\text{ cm}^{-1}$ , appears in both the concentrated and more dilute acids, but not at moderate concentrations. It is very weak in  $\text{H}_2\text{SO}_4$ , and owing to the rather more difficult experimental conditions was not visible in strong  $\text{D}_2\text{SO}_4$ . Most authors reporting this line in the spectrum of the strong acid stress its distinct character, and state that it must not be confused with the strong  $\text{SO}_4^{--}$  line of the same value in the dilute solution. Yet, as Cartwright<sup>7</sup> points out, there is every reason to assume the presence of the hydrate  $(\text{SO}_4)^{--}(\text{OH})_2^{++}$  in sulphuric acid containing only a trace of water, therefore one would expect the characteristic sulphate ion frequency to appear faintly in the spectrum of the more concentrated acid. It is significant that Bell and Jeppesen, who seem to have worked with the most anhydrous acid (f.p.  $10.3^\circ$ ), do not obtain this line from their 100 per cent. acid but find it appearing as soon as a small amount of water is added. In the circumstances one must assume that line (e) has the same origin throughout, *viz.*, the  $\text{SO}_4^{--}$  ion, and that its presence in the spectrum of concentrated  $\text{H}_2\text{SO}_4$  confirms the presence of the ionic hydrate.

Line (f), the bisulphate ion frequency of  $1050\text{ cm}^{-1}$ , is rather more difficult to explain, particularly since its value is not depressed in  $\text{D}_2\text{SO}_4$ . Woodward and Horner consider that it exhibits a real dilution shift, but the experiments with the "heavy" acid, in which there is practically no dilution effect, indicate that the variations in  $\text{H}_2\text{SO}_4$  have no real significance. Cartwright suggests that the bisulphate ion is hydrated in solution and is of the composition  $(\text{H}_2\text{SO}_5)^-$ , quoting in support of this view data obtained from freezing-point/composition and viscosity/composition curves. From the standpoint of the Raman spectrum the existence of such a hydrate is very doubtful, since one would then expect a real isotope shift instead of the observed zero effect. It seems most probable that the line (f) arises from a valency vibration involving only the oxygen atoms, and is thus closely related to the  $985\text{ cm}^{-1}$   $\text{SO}_4^{--}$  frequency, and the frequencies at approximately  $1055\text{ cm}^{-1}$  in nitrates and carbonates.

Since it is difficult to obtain reasonable exact values for the three highest frequencies (g), (h), and (i), isotope or dilution effects cannot be verified. The results for  $\text{D}_2\text{SO}_4$  do show that (g) and (h) are distinct, separate lines. Most investigators find that these lines become less intense as dilution proceeds, but in  $\text{D}_2\text{SO}_4$  no appreciable variation in intensity was detected. Bell and Jeppesen alone observed this approximately constant intensity in  $\text{H}_2\text{SO}_4$ . In the absence of more precise frequency data these lines cannot be definitely associated with any particular ion or group.

<sup>9</sup> *Phil. Mag.*, 1935, 20, 621.

### Summary.

The Raman spectrum of  $D_2SO_4$  in the pure form, and at various concentrations in  $D_2O$  has been determined. Certain of the lines show small isotope shifts, together with frequency changes on dilution. By comparing these with the corresponding values in  $H_2SO_4$  evidence is obtained in support of the view of Woodward and Horner that many of the lines are composite in character. The generally accepted assignments are reviewed from the standpoint of the results obtained for  $D_2SO_4$ .

The author wishes to record his thanks to Dr. W. R. Angus for much helpful advice, and to the Department of Scientific and Industrial Research for a grant.

## THE ELECTROPHORETIC MOBILITY OF PURIFIED TRISTEARIN. PART I. THE ACID REGION, $p_H$ 2 TO 7.

By A. L. ROBERTS.

(Communicated by W. C. M. LEWIS, F.R.S.)

Received 5th October, 1936.

In this paper measurements of the electrophoretic behaviour of dispersions of tristearin are described. It was desired to obtain a reproducible "inert" surface which could be subjected to a detailed examination as the basis of similar measurements on other long chain compounds. Tristearin is a naturally occurring fat which is not reactive and which might be expected to carry a higher charge than a hydrocarbon. The mobility has been examined in the presence of various salts. Particular care has been taken to ascertain the effect of the hydrogen ion concentration on the mobility. The work described has shown that over the range  $p_H$  5 — 7, which includes that of "distilled" water, the mobility varies rapidly with  $p_H$  and hence, in attempting to find the effects of added salts, it is essential that the hydrogen ion concentration should be controlled as accurately as possible. The effect of  $p_H$  change would obviously be most marked with the alkali metal salts of weak acids and it seems that the significance of the  $p_H$  in the case of inert surfaces which owe their charge not inconsiderably to the hydroxyl ion has been frequently overlooked.

### Experimental.

The electrophoresis measurements were carried out macroscopically in the apparatus described by Price and Lewis<sup>1</sup> using the moving boundary method, which has the advantage of accurate temperature control. The main U-tube, of quartz, 1 cm. in diameter, was fitted with side arms

<sup>1</sup> Price and Lewis, *Trans. Faraday Soc.*, 1933, 29, 775.

of sufficient length to prevent the products of electrolysis from the working electrodes from migrating into the body of the apparatus during a determination. The main electrodes, an anode of zinc and a cathode of lead coated electrolytically with lead peroxide, eliminated gas evolution and its kindred disturbances.\*

For measuring the potential gradient across the central part of the U-tube small platinum electrodes, which were quite reproducible, were introduced at either end of the main arms. The effective distance between these had been ascertained by conductivity measurements.

To determine the potential gradient across the main tube a known potential from a battery was put across the subsidiary electrodes and the potential in the tube was adjusted to be equal to this by varying the voltage between the outside electrodes. A balance method was employed to match the potentials, the null point being found with the aid of a capillary electrometer. It was necessary to reset the outside voltage at ten-minute intervals, or more frequently in acid solutions.

To eliminate disintegration or blurring of the boundaries through temperature variations, the tube was suspended in a glass trough of water, maintained within  $0.1^{\circ}\text{C}$ . of  $25^{\circ}\text{C}$ . by an efficient circulating system from a thermostat. All solutions and emulsions were also brought to  $25.0^{\circ}\text{C}$ . before introduction into the apparatus.

The boundaries were examined through a telescope placed 1 metre from the apparatus. On account of the thinness of the emulsions the tube was illuminated by a brilliant light placed obliquely at the rear of the trough.

The electrophoretic data obtained are accurate to approximately 4 per cent.

The  $p_H$  values were determined by the glass electrode at  $25^{\circ}\text{C}$ . in an oil thermostat. The gold-quinhydrone electrode was also utilised for some of the results in buffer solutions. The results obtained are accurate to 0.01  $p_H$  unit for buffer solutions and for values below  $p_H$  4 in unbuffered solutions. For unbuffered solutions the error is not greater than 0.05 unit up to  $p_H$  5.5 or 0.1 unit above this value.

### Purification of the Tristearin.

After a preliminary examination of several preparations, the fat employed was one specially prepared and kindly supplied by Messrs. Lever Bros. Ltd. This product was a smooth white odourless solid with an iodine value of 0.6. It contained a few per cent. of tripalmitin but was very free from acids or unsaturated compounds. It was further purified by dissolving 100 gm. in 300 ml. of pure boiling chloroform and allowing the solution to cool slowly. As soon as a fair crop of solid had been precipitated it was drained off and washed once with a little ice-cold chloroform. By removing the yield in small quantities the liability of the mother liquor being trapped in the solid was reduced to a minimum. The final separation of the fat was carried out by cooling in melting ice. The recrystallizations were continued until no further alteration in the product could be detected, the mobility of an emulsion made from each fraction in the presence of  $N/100$  secondary sodium citrate being used as the criterion of electrophoretic purity. It was found that two recrystallizations of the first crops sufficed to give a product of constant mobility. The mobility, which at  $20^{\circ}\text{C}$ . was  $11.6 \times 10^{-8}$  cm./sec. under 1 volt/cm for the original substance, fell after two recrystallisations to the constant value of  $7.6 \times 10^{-8}$ . The final product was quite odourless and gave a colourless solution in chloroform. As a further precaution some of this

\* For the measurements with ferrocyanide solutions the zinc electrode is inadmissible. It was replaced by a silver-silver nitrate electrode with a saturated ammonium nitrate bridge. Suitable precautions were taken to prevent the ammonium nitrate from entering the U-tube.

purified tristearin was recrystallised from "analar" acetone, which had been twice redistilled. The mobility of the fat was found to be unaffected.

### Preparation of the Emulsions.

In the investigation of the various fractions obtained in the purification, the dispersions were made up in an identical manner by the addition of 0.6 gm. of fat, in 10 ml. of boiling alcohol, to one litre of distilled water at 75° C. This temperature was chosen because it is just above the melting-point of tristearin; below this temperature rapid solidification might produce the meta-stable  $\alpha$ -form. 75° C., however, is below the boiling-point of the alcohol and hence there is approximately 1 per cent. of alcohol in the emulsions. It is possible that this might exert a noticeable effect on the mobility. Emulsions were therefore made up by adding the alcoholic solution of tristearin to water which was boiling vigorously. In this way the alcohol was almost completely driven off at the moment of contact with the water. Finally, a dispersion was boiled continuously for four hours, the evaporation losses being made up with distilled water, before being allowed to cool. In every case it was observed that the mobility was unaltered and hence the trace of alcohol has no measurable effect. All dispersions were allowed to stand overnight before buffering and using.

It follows from the fact that prolonged boiling has no effect that there is no aging effect in the tristearin emulsions. In practice it has been observed that mobility measurements made after one week are the same as those made after 24 hours.

### (a) The Effect of $p_H$ on Emulsions of the Purified Fat in Various Buffer Solutions.

The accuracy with which the mobility— $p_H$  curve can be determined is, to a large extent, dependent upon the matching of the  $p_H$  of the emulsion and the clear liquid and upon the correct measurement of the various  $p_H$  values. It is, therefore, most convenient to carry out the determinations in buffered solutions and the effect of added electrolytes must be closely examined. For example, using a purified engine oil, Powis<sup>2</sup> found that at  $N/100$  concentration of sodium chloride the mobility is almost the same as in the absence of any electrolyte, while Tuorila,<sup>3</sup> working on a hydrocarbon, observed that at this concentration of

<sup>3</sup> Tuorila, *Kolloidchem. Beih.*, 1928, 27, 44.

sodium chloride the mobility had been reduced to about half that for electrolyte-free emulsions.

The buffers employed were citrate mixtures,

FIG. 2.—The mobility of Tristearin in Potassium Phosphate and Phthalate Buffers.

tained at a fixed concentration. The phosphate and phthalate buffers do not have this disability. A satisfactory degree of buffering with either of these substances is obtainable between  $p_H$  3 and 7, while keeping the concentration of the alkali metal at  $N/100$  throughout. For the higher  $p_H$  values, increasing amounts of the potassium salts were replaced by equivalent quantities of caustic soda whilst  $p_H$ 's below 4 were secured by the addition of small amounts of hydrochloric acid.

The supernatant liquid was in every case buffer solution of the same ionic composition as the dispersion. As the density of the dispersions is the same as that of the supernatant liquid it was found necessary for all emulsions to contain 2 per cent. of sucrose in order to obtain clear boundaries. This small amount of sugar has been shown by Northrop and Cullen<sup>4</sup> to have a negligible effect upon the electrophoretic rate.

Table I. shows a typical example of a determination.

acetate-acetic acid solutions, and potassium phosphate and potassium phthalate solutions. The citrate used was that of Sørensen, diluted tenfold with emulsion or water as desired. The maximum concentration of sodium ion present was thus  $N/50$  at  $p_H$  5.2. The acetate solutions were adjusted to be  $N/100$  with respect to the sodium acetate, the  $p_H$  being reduced by progressively replacing this salt with an equivalent amount of acetic acid. Both of these buffer systems suffer from the disadvantage that the concentration of the added salt is different at different  $p_H$  values. It is, however, not possible to cover a sufficiently wide  $p_H$  range if the sodium salt is main-

It will be seen from the mobility— $p_H$  curves (Figs. I. and II.) in the presence of the different buffer solutions that the added electrolytes exhibit specific effects although the chief factor in determining the mobility is clearly the  $p_H$  value. In phosphate and phthalate solutions the mobility is the same for a given  $p_H$  value, except for the slight divergence at low  $p_H$ . In these two cases the amount of alkali metal salt present is the same throughout. This points to the possibility that in the case of these buffers the added anion is relatively unimportant compared with the effect arising from alteration in the concentration of the cation.

FIG. 3.—The mobility of Tristearin in N/100 Citrate Buffer, and the effect of replacing the Citrate ion by an equivalent amount of Chloride ion.

### (b) The Effect of $p_H$ on Tristearin Emulsions in the Presence of Sodium and Potassium Chlorides.

In order to obtain further information on the rôle played by the anion in the tristearin dispersions mobilities were also determined in sodium and potassium chlorides. Fig. 3 shows mobilities in the presence of sodium chloride, the concentration of which was so arranged that the sodium ion concentration was the same as that in the citrate buffer at the same  $p_H$  value. The  $p_H$  values of the emulsions in the sodium chloride solutions have been attained by the addition of the appropriate quantities of hydrochloric acid. In the buffer solution the ions present are hydrogen, sodium, chloride and citrate, whilst in this case they are hydrogen, sodium and chloride. As the hydrogen and sodium are adjusted to be the same in both, the second case corresponds effectively to the replacement of the citrate ion of the citrate buffered dispersions by the chloride ion. Fig. 3 illustrates the behaviour.

FIG. 4.—The mobility of Tristearin in N/100 Sodium and Potassium salts.

corresponds effectively to the replacement of the citrate ion of the citrate buffered dispersions by the chloride ion. Fig. 3 illustrates the behaviour.

It will be noticed that, while the curves run together at  $p_H$  5.2, in more acid solutions that for the emulsions buffered with citrate lies somewhat below the other.

Mobility measurements were also made using emulsions in which the concentration of added sodium chloride was kept at  $N/100$  throughout, the  $p_H$  again being obtained by the addition of hydrochloric acid. A few similar points are shown for potassium chloride and sodium bromide. (See Fig. 4.)

It is seen that the points for  $N/100$  potassium chloride and  $N/100$  potassium phosphate buffer fall upon the same curve. In the same manner the mobility- $p_H$  curves for  $N/100$  sodium chloride and  $N/100$  sodium bromide are identical. Moreover the curves in the presence of  $N/100$  sodium salt lie somewhat above those for  $N/100$  potassium salt. That the potassium ion has a rather greater discharging effect than the sodium ion under similar conditions has frequently been observed in the case of "inert" surfaces.<sup>6</sup> The effect is always small. In the case of tristearin, whilst the steepness of the mobility- $p_H$  curves above  $p_H$  5 makes it difficult to distinguish between the sodium and potassium curves, below this value the difference appears to be roughly constant, being about one mobility unit.

The most striking conclusion to be drawn from the above results is the remarkable similarity in the effects of the different anions, particularly at the higher  $p_H$  values. It is not necessarily to be inferred from this behaviour in respect of mobility that the anions are without effect upon the charge density. This point is considered later.

### (c) The Mobility of Tristearin at Constant $p_H$ at Different Salt Concentrations.

In this section the effect of salts at different concentrations on the mobility of tristearin dispersions is recorded. Care has been taken to

FIG. 5.—The effect of Sodium salts on the mobility of Tristearin.

chloride, citrate and acetate. The mobility is also shown at  $p_H$  4 for sodium chloride and citrate as well as for the potassium salts previously employed (Fig. 6). The  $p_H$  value of 4 was chosen for the majority of

maintain the  $p_H$  values constant at all concentrations of the salts for, clearly, if a salt of a weak acid be added to an emulsion at  $p_H$  5.6, the  $p_H$  value of the emulsion will be displaced to a more alkaline value and, since in this region the mobility is very sensitive to  $p_H$  change, erroneous effects will be observed unless precautions are taken to keep the  $p_H$  constant.

In Fig. 5 the mobility is given at  $p_H$  5.4 approximately for different concentrations of sodium

<sup>6</sup> Lachs and Biczysk, *Z. physik. Chem.*, 1930, 148, 441; Briggs, *J. Physic. Chem.*, 1928, 32, 1646; Tuorila, *loc. cit.*<sup>6</sup>

the concentration curves because, while the mobility is still reasonably large, the hydroxyl ion concentration, which seems to be an important factor in the determination of the charge, is sufficiently reduced to provide a fair opportunity for the primary adsorption of other ions.

In addition to the potassium chloride, phosphate and phthalate curves a curve has been obtained for various concentrations of potassium ferrocyanide, and for barium chloride.

For the measurements carried out at  $p_H$  5.4 the  $p_H$  value was attained by the introduction of small amounts of very dilute hydrochloric acid in the case of the sodium chloride. For the sodium citrate it was found sufficient to dilute the stock solution of secondary sodium citrate with water or emulsion as required. The sodium acetate used was a mixture of nine parts of  $N/10$  sodium acetate and one part of  $N/10$  acetic acid, suitably diluted.

At  $p_H$  4 the  $p_H$  is readily attained for sodium chloride, and for potassium chloride, phosphate and phthalate, and also for barium chloride, a slight adjustment being made with dilute hydrochloric acid. The sodium citrate was a mixture of  $N/10$  secondary sodium citrate and  $N/10$  hydrochloric acid containing 57 ml. of the salt solution to 43 ml. of acid solution and having a  $p_H$  of 4. This was then diluted as necessary, additional quantities of acid being added at the higher dilutions. For the ferrocyanide measurements also it was necessary to add one part of  $N/10$  hydrochloric acid to 10 of  $N/10$  potassium ferrocyanide solution and dilute to the required strength.

The experimental data are given in Figs. 5 and 6. If the fact that the mobility is sensitive

to small  $p_H$  changes at  $p_H$  5.4 be borne in mind, it may be concluded that at this  $p_H$  the anions exhibit only minor specific effects and that the concentration curve is substantially the same in the three cases. At  $p_H$  4, however, the sensitivity of the mobility to  $p_H$  is not so marked and the difference observed in the mobilities of sodium chloride and citrate respectively must be taken as a real though small effect. Similarly in the case of the potassium salts examined all, except phthalate, give the same curve. It is interesting to note that, when the  $p_H$  is kept constant, the results for the mobilities in ferrocyanide solutions are identical with those for the chloride solutions. Large specific effects have frequently been assumed for this ion and, in some cases at least, it seems likely that the  $p_H$  alteration has been overlooked. It must not be assumed, however, that the substantial identity in the mobilities of potassium chloride and potassium ferrocyanide infers an identity of charge also, for the thickness of the diffuse double layer is by no means the same for both.

FIG. 6.—The effect of Potassium salts on the mobility of Tristearin at  $p_H$  4 and a comparison with that of Barium Chloride.

**(d) The Mobility of Tristearin Dispersions in the Presence of the Chlorides of the Alkali Metals.**

In the previous sections it has been found that, other things being equal,

FIG. 7.—The effect of the alkali metal Chlorides on the mobility of Tristearin at  $p_H$  5.0.

the different cations. Clearly, however, the caesium ion lowers the mobility more than the lithium ion.

**(e) The Mobility of Dispersions of Tristearin in the Absence of Added Salts or Buffers.**

As the previous results have shown, there is an appreciable lowering of the mobility of the fat in the presence of added salts as compared with the mobility of salt-free emulsions. Here a brief record is given of the data obtained when all electrolyte is eliminated except the small amount of acid, or for the highest  $p_H$  values, of alkali, necessary to obtain the appropriate  $p_H$  values. In the absence of other electrolytes, however, it becomes essential to investigate the effect of carbon dioxide, or more particularly, of the bicarbonate ion, in the emulsions. It has been found that many "inert" surfaces increase their charge on allowing the solutions to come into equilibrium with the carbon dioxide of the atmosphere. (cf. Abramson.)<sup>6</sup>

A preliminary investigation of the effect of dissolved carbon dioxide was carried out in the presence of citrate buffer, but no alteration in mobility could be detected between emulsions which were carbon dioxide-free and those which had been exposed to the atmosphere. Continuing the examination more closely, the buffer, which might mask or prevent any effect, was dispensed with. The carbon dioxide-free emulsions were made from freshly distilled boiling water, and immediately after adding the tristearin the flask was tightly stoppered and allowed to cool whilst a stream of washed carbon dioxide-free air was drawn through. For the supernatant liquid employed in the U-tube boiling distilled water was aspirated in the same manner. Mobility measurements were made on the emulsions between  $p_H$  6.9 and 2 allowing them to make contact with the atmosphere for the shortest time possible. The mobility- $p_H$  curve was plotted, the different  $p_H$  values being obtained by adding suitable

<sup>6</sup> Abramson, *Electrokinetic Phenomena*, p. 133.

amounts of dilute hydrochloric acid, or above  $p_H$  6 of dilute caustic soda. The points were quite reproducible for three separate emulsions.

The above procedure was then repeated, except that in this case the air drawn through had not been freed of its carbon dioxide. The points fall closely upon the first curve and illustrate that under these conditions the effect of the bicarbonate ion is negligible.

Finally, an emulsion was prepared by adding the alcoholic solution to boiling, originally faintly alkaline, water, through which a rapid stream of washed carbon dioxide was being passed. This insured the presence of a fair concentration of bicarbonate ion in the water at the time of formation of the dispersion. The current of gas was continued until the whole attained room temperature. The  $p_H$  was varied as before by adding acid or alkali, but in this case the initial  $p_H$  of the stock emulsion was about 4.3. There was also a considerable amount of carbon dioxide in the dissolved gas state. Thus, on the introduction of caustic soda, relatively large amounts were necessary to obtain a reasonable  $p_H$  change on account of the buffering action of the carbonic acid present and the sodium bicarbonate formed. The mobilities are, therefore, somewhat depressed at the higher  $p_H$  values due to the effect of the increasing cation concentration. The experimental values are illustrated in Fig. 8. At lower  $p_H$  values the mobility for the carbon dioxide saturated emulsion is higher than that of the carbon dioxide-free emulsion. This effect is small and is not important. Fig. 8 also shows that the mobility curve in the "absence" of electrolyte lies above the corresponding curve in which there is a constant concentration ( $N/100$ ) of sodium chloride.

FIG. 8.—The mobility of Tristearin in electrolyte-free emulsions.

### Discussion.

The general conclusion to be drawn from a consideration of the foregoing experiments is that the mobility is affected by added salts but that there is relatively little specific difference between the effects of salts containing cations of the same valency. As far as the electrophoretic mobility of the fat is concerned the effect of  $p_H$  on it stands out as the main controlling factor.

The mobility, however, is a function of the electrokinetic charge density and it would seem on general grounds that the latter should be regarded as the more fundamental property of the system. When the experimental facts are regarded from the point of view of the charge density they assume quite a different significance, but it is first necessary to consider the relationship between the two quantities, electrokinetic charge density and electrophoretic mobility.

The electrokinetic charge density is, of course, equal in magnitude and of opposite sign to the charge in the diffuse double layer, and the latter was first systematically treated by Gouy.<sup>7</sup> He obtained an expression which gives a connection between the electrokinetic charge and the  $\zeta$ -potential. The treatment is summarised by Müller<sup>8</sup> and for a uni-univalent electrolyte and a flat double layer the expression reduces to

$$\sigma = 2\alpha \sqrt{c} \sinh \zeta/2\beta$$

where  $\sigma$  is the electrokinetic charge density,

$\zeta$  is the electrokinetic potential,

$c$  is the concentration of electrolyte,

and  $\alpha$  and  $\beta$  are constants.

In order to relate  $\sigma$  and  $u$ , the mobility, using the above equation it is necessary to connect  $\zeta$  and  $u$ . The Smoluchowski relation

$$\zeta = \frac{4\pi\eta u}{D}$$

where  $\eta$  is the viscosity,  $u$ , the mobility under unit potential grad., and  $D$  the dielectric constant, is usually employed. This expression, however, is open to criticism and the connection between  $\zeta$  and  $u$  has been redetermined more rigorously by D. C. Henry.<sup>9</sup> Combined with the simple equation for the capacity of a concentric sphere condenser Henry gives the relationship between  $u$  and  $\sigma$  as

$$\sigma = \frac{u\eta (1 + \kappa a)}{a} \cdot \frac{1}{f(\kappa a)}$$

in which  $f(\kappa a)$  is a quantity depending upon  $\kappa$ , the reciprocal of the "thickness" of the diffuse double layer, and  $a$  is the radius of the particle. This equation is more satisfactory than the Gouy expression for the lower values of  $\zeta$ , or  $u$ , and when  $\kappa a$  is less than 300. Above the latter value the two expressions are the same but at higher potentials the equations of the electric field which are used by Henry begin to fail.

In the case of the tristearin dispersions it is legitimate to employ the usual value of the mean radius of the particles for dilute emulsions of this nature, namely about  $5 \times 10^{-5}$  cm. and the correction,  $f(\kappa a)$ , is only of importance for the salt-free emulsions.

Calculation shows that, in the absence of salt, the  $\sigma$  increases with decrease in  $p_H$ ; when salt is present, however,  $\sigma$  rises very rapidly indeed either with increasing salt concentration at fixed  $p_H$  value or with increasing  $p_H$  at fixed salt concentration. With respect to the variation in charge density with  $p_H$  the values of  $\sigma$  have been calculated

<sup>7</sup> Gouy, *J. Physique*, 1910, 9, 457.

<sup>8</sup> Müller, *Cold Spring Harbor Symposium of Quantitative Biology*, p. 1 (1933).

<sup>9</sup> Henry, *Proc. Roy. Soc., A*, 1931, 133, 124.

at different  $p_H$  values in the presence of different concentrations of sodium chloride and also for the salt-free case. Inspection of Table II. shows that  $\sigma$  is 61 e.s.u. at  $p_H$  6 and 82 e.s.u. at  $p_H$  5 in the absence of any sodium chloride. In  $N/100$  sodium chloride at  $p_H$  6  $\sigma$  is 1790 e.s.u. and falls to 870 e.s.u. at  $p_H$  5. Now if the primary charge were due solely to the anions present, i.e. hydroxyl and chloride, and if further the secondary layer were entirely diffuse, as postulated by Gouy, this fall must be due to removal of the hydroxyl ion from the surface, the chloride ion charge (if any) probably remaining constant. The

loss, however, is far greater than the total charge density due to the hydroxyl ion, as calculated from the salt-free case.\* It follows, therefore, that the total density of charge on the primary layer must be considerably greater than the value of  $\sigma$  calculated but that at the same time a proportion of the cations present have effectively annulled a corresponding part of this charge density. This is in agreement with the concept of Stern<sup>10</sup> in which a secondary rigid layer is postulated as well as a diffuse layer. Then in the case of the dispersions containing a constant salt concentration the fall in electrophoretic charge density with decrease in  $p_H$  may be explained assuming that hydrogen ions enter the secondary rigid layer or that the primary charge density decreases due to loss of hydroxyl ion. It is to be expected that the amount of hydrogen ion so adsorbed will be a function of the initial magnitude of the effective primary charge, and inspection of the charge density table shows that the fractional fall in  $\sigma$  with fall on  $p_H$  at the different salt concentrations is indeed approximately the same in each case. Attempts, however, to fit the experimental values to a simple Langmuir adsorption equation, of the type predicted by the law of mass action, fail.†

Turning to the case of increasing salt concentration whilst maintain-

<sup>10</sup> Stern, *Z. Elektrochem.*, 1924, 30, 508.

\* Although in this case the charge density is increasing with decrease in  $p_H$ , a maximum must be passed through as eventually, at  $p_H$  2.2 the mobility, and therefore the electro-kinetic charge density, falls to zero. Further, in the presence of NaCl the mobility was likewise found to reach zero value at the same  $p_H$ , viz., 2.2, indicating that the "discharging" efficiency of hydrogen ion is far greater than that of the alkali metal ion.

† It seems reasonable to assume that the amount of a cation rigidly adsorbed in the secondary layer, besides being a function of the bulk concentration of that ion, would be affected by the magnitude of the primary charge. Thus, on increasing the primary charge, by raising the concentration of the sodium chloride, it is to be expected that, even though the hydrogen ion concentration were maintained at a constant value in the bulk, the amount of this ion rigidly adsorbed would increase. Such an increase would account for the failure of the simple adsorption equation.

ing a constant  $p_H$  value, here the concentrations of the two added ions, sodium and chloride, are increasing at the same rate, but also, probably the amount of hydrogen ion adsorbed will be governed by the increase in the concentration of the sodium chloride.

In addition to the data just discussed, in which we are concerned chiefly with the effect of altering the  $p_H$  in the presence of a single

cases there is a decrease in mobility with increasing salt content, particularly so in the case of  $BaCl_2$ ). Table III. A shows that the lightly hydrated caesium ion finds its way more readily into the rigid part of the secondary layer than does the heavily hydrated lithium or sodium ion. In Table III. B the case of  $K_4Fe(CN)_6$  is of special importance as showing either a primary adsorbability of the multivalent anion, or an enhanced removal of  $H^+$  ion by union with the ferro-cyanide anion. The charge density in this case is appreciably greater than that for KCl although the mobilities in these two cases are indistinguishable. The  $\kappa$  term is of course greater in the case of the ferro-cyanide.

### Summary.

(1) The electrophoretic mobility of purified tristearin in different buffer solutions has been examined as a function of  $p_H$  between the  $p_H$  values 2 and 7. The variation of the mobility with  $p_H$  in sodium and potassium chloride solutions has likewise been measured.

(2) The effects of different added anions has been found at fixed  $p_H$  values. The mobility is found to be chiefly a function of the salt concentrations rather than of the individual ions.

(3) The mobility has been observed in the alkali metal chloride solutions at constant  $p_H$ . The lyotropic series appears to hold but the differences are slight.

(4) The variation of mobility with  $p_H$  in the absence of any electrolyte, except that necessary to attain the  $p_H$  values has been determined. The effect of small amounts of dissolved  $CO_2$  is found to be negligible.

typical uni-univalent salt, NaCl, the mobility data shown in the graphs likewise permit of a comparison of various salts at a fixed  $p_H$ . The resulting charge densities are summarised in Table III. (The effects produced by NaCl and LiCl are indistinguishable.)

Considering the results of both sections of the above table it will be seen that in all cases there is an increase in  $\sigma$  with increase in salt concentration, even in the case of barium chloride, although in the latter case as might be expected the influence of the barium ion acts as a depressing agent. (It will be recalled that in all

(5) In connection with the relation between the electro-kinetic charge density  $\sigma$  and the mobility, calculation shows that  $\sigma$  increases with fall in  $p_H$  in the "absence" of electrolyte, but decreases with fall in  $p_H$  if salt is present. Further,  $\sigma$  is found to increase with rising salt concentration at constant  $p_H$ .

(6) In order to account for the variation in  $\sigma$  it is necessary to assume either primary adsorption of the added anions, or exchange of  $H^+$  ion in the rigid secondary layer by the added cations, producing a less tightly bound system, thus increasing the effective electrokinetic charge. Under comparable conditions as regards concentration,  $H^+$  ion is much more strongly adsorbed into the rigid secondary layer than is any other cation. Exchange, in the sense of removal of  $H^+$  ion, is only brought about when the concentration of the added cation is much greater than that of  $H^+$  ion.

(7) It is concluded that the amount of hydrogen ion adsorbed in the rigid secondary layer is a function of the effective primary charge as well as of  $p_H$ .

## THE EFFECT OF DILUTE HYDROCHLORIC ACID ON THE SURFACE TENSIONS OF AQUEOUS SALT SOLUTIONS.

BY J. W. BELTON.

*Received 8th October, 1936.*

The calculation of the adsorption of the components at the surface of a ternary solution involves a knowledge of the change in surface tension with the concentration of each solute, and of the variation of the activity coefficients of the components with the composition of the solution. These data are frequently difficult to obtain, but in the case of certain solutions, such as those containing hydrochloric acid and salts, simplifications may be made and the surface adsorptions calculated.<sup>1</sup>

It has been shown previously<sup>2</sup> that the presence of 0.1 *M* hydrochloric acid produces a measurable change in the surface tensions of aqueous solutions of sodium and potassium chlorides, the effect increasing with increasing salt concentration. These measurements have now been extended to solutions containing other salts and the surface adsorptions calculated. The surface tension of the acid solution alone is only 0.02 dyne/cm. less than that of pure water, an amount of the order of the experimental error; it might be therefore expected that the presence of dilute acid in strong salt solutions could be neglected. The effect of the two solutes on the surface tension is, however, not equal to the sum of the effects produced by each when present separately.

### Experimental.

The surface tensions were measured by the bubble pressure method previously described,<sup>3</sup> and were calculated from the expression

$$\gamma = \frac{rg}{2} \left( h\rho - \frac{2}{3}r\rho \right) \quad \dots \quad (1)$$

where  $r$  is the radius of the jet,  $g$  is 981.2 cms./sec.<sup>2</sup>,  $h$  is the maximum bubble pressure in cms. of butyl phthalate, the manometric liquid,  $\rho$  is

<sup>1</sup> Belton, *Trans. Faraday Soc.*, 1935, 31, 1413.

<sup>2</sup> *Ibid.*, 1648.

the density of butyl phthalate at 25° (1.0434 gms./c.c.), and  $\rho_1$  the density of the solution under examination. Two jets were used in this investigation, one of radius 0.0102 cm., the other 0.0104 cm.; both were broken

\* Last column in b refers to  $h_1'$  and not  $h_1$ .

clean and were circular in cross-section. The surface tensions of pure water and of pure benzene found with both jets agreed with the standard values. Solutions were made up by weight in stoppered flasks from Analar salts, some of which had been further treated for the removal of water, and from a stock solution of 0.1 *M* hydrochloric acid. In the case of barium chloride, sodium perchlorate and sodium dithionate the hydrated salt was used and the solution made 0.1 *M* with respect to hydrochloric acid by the addition of a calculated weight of acid of strength greater than 0.1 *M*. For purposes of comparison, parallel measurements were made on salt solutions not containing acid. All measurements were made at 25°.

The results obtained are given in Table I. (a) and (b) which refer to salt solutions and to salt-acid solutions respectively. Each part of the Table gives the salt present, its concentration, *m*, in moles per 1000 gms. of water, the manometric reading, the surface tension ( $\gamma$ ), the surface tension increment,  $\Delta\gamma$ , ( $\gamma_0 = 72.01$  dynes/cm.), and the value of *k* calculated from it.

In each case the presence of the acid reduces the surface tension, the effect increasing with increasing salt concentration. The surface tensions of the salt solutions are given by the relation

$$\gamma - \gamma_0 = k_1 m_1$$

where  $k_1$  is a constant, while those of the acid-salt mixtures are given by a similar relation in which the constant ( $k_1'$ ) is less than  $k_1$ .

### Application of the Gibbs Equation.

In the salt solutions water is positively adsorbed at the surface, while in hydrochloric acid solutions, for which the surface tension decreases with increasing acid concentration, the acid is positively adsorbed. In solutions containing both components we may expect both water and acid to be positively adsorbed. According to the Gibbs equation

$$d\gamma = -\Gamma_1 d\mu_1 - \Gamma_2 d\mu_2 - \Gamma_3 d\mu_3 \quad (2)$$

in which  $\Gamma_1$ ,  $\Gamma_2$  and  $\Gamma_3$  are the surface adsorptions of salt, acid and water respectively, and  $\mu_1$ ,  $\mu_2$  and  $\mu_3$  are their chemical potentials. If the dividing surface is drawn so that the concentration of salt is zero, this becomes

$$d\gamma = -\Gamma_2 d\mu_2 - \Gamma_3 d\mu_3 \quad (3)$$

A relation between the mole fractions (*n*) of the components and their chemical potentials is given by the Duhem-Margules equation, according to which

$$n_1 d\mu_1 + n_2 d\mu_2 + n_3 d\mu_3 = 0 \quad (4)$$

Substituting for  $-d\mu_3$  in (3) we obtain

$$d\gamma = -\Gamma_2 d\mu_2 + \Gamma_3 \left( \frac{n_1}{n_3} d\mu_1 + \frac{n_2}{n_3} d\mu_2 \right) \quad (5)$$

$$= -\Gamma_2 2RT \, d \log f_2 m_2 + \Gamma_3 \frac{m_1}{55.55} 2RT \, d \log f_1 m_1 \\ + \Gamma_3 \frac{m_2}{55.55} 2RT \, d \log f_2 m_2 \quad (6)$$

where *f* is the appropriate activity coefficient. If the acid concentration is kept constant and that of the salt varied

$$\left( \frac{d\gamma}{dm_1} \right)_{m_2} = -\Gamma_2 2RT \left( \frac{\partial \log f_2}{\partial m_1} \right)_{m_2} + \Gamma_3 \frac{m_1}{55.55} 2RT \left( \frac{1}{m_1} + \left( \frac{\partial \log f_1}{\partial m_1} \right)_{m_2} \right) \\ + \Gamma_3 \frac{m_2}{55.55} 2RT \left( \frac{\partial \log f_2}{\partial m_1} \right)_{m_2} \quad (7)$$

The acid adsorption,  $\Gamma_2$ , is much smaller than  $\Gamma_1$  (of the order  $10^{-12}$ ), and consequently the first term on the right-hand side may be neglected and (7) becomes

$$\left(\frac{\partial \gamma}{\partial m_1}\right)_{m_2} = \frac{\Gamma_1 2RT}{55 \cdot 55} \left(1 + m_1 \left(\frac{\partial \log f_1}{\partial m_1}\right)_{m_2} + m_2 \left(\frac{\partial \log f_2}{\partial m_1}\right)_{m_2}\right). \quad (8)$$

The surface concentration of water for a solution without acid is given by the Gibbs equation applied to a system of two components

$$d\gamma = - {}_0\Gamma_3 d\mu_3$$

or 
$$\frac{d\gamma}{dm} = - {}_0\Gamma_3 \frac{m_1}{55 \cdot 55} 2RT \left(\frac{1}{m_1} + \frac{d \log f_1}{dm}\right) \quad (9)$$

Further  $d\gamma/dm = k_1$  the experimentally determined constant. If the effect of 0.1 *M* hydrochloric acid on the  $\partial \log f/\partial m$  term is neglected, and (8) and (9) are combined, we obtain

$$\left(\frac{\partial \gamma}{\partial m_1}\right)_{m_2} = \Gamma_3 \left[-\frac{k_1}{{}_0\Gamma_3} + \frac{m_2}{55 \cdot 55} 2RT \left(\frac{\partial \log f_2}{\partial m_1}\right)_{m_2}\right] \quad (10)$$

from which values of  $\Gamma_3$  may be computed. Values of  ${}_0\Gamma_3$  may be obtained directly from the vapour pressure ( $p$ ) of water over the solutions

$${}_0\Gamma_3 = -\frac{d\gamma}{d\mu_3} = -\frac{d\gamma}{RT d \log p} = -\frac{p}{RT} \frac{d\gamma}{dp} \quad (11)$$

Hence

$$\Gamma_3 = k_1' \left/ \left[ k_1 \frac{RT}{p} \cdot \frac{\Delta p}{\Delta \gamma} + \frac{m_2}{55 \cdot 55} 2RT \left(\frac{\partial \log f_2}{\partial m_1}\right)_{m_2} \right] \right. \quad (12)$$

The values of  $\Gamma_3$  in moles/sq. cm. calculated in this way are given in Table II. The experimental data for sodium and potassium chloride solutions have been taken from the previous paper.<sup>3</sup> The vapour pressures of water for solutions of sodium, potassium and lithium chlorides have been taken from the measurements of Pease and Nelson,<sup>3</sup> and for solutions of calcium, strontium and barium chlorides from the data of Hepburn.<sup>4</sup> The values of  $(\partial \log f_2/\partial m_1)_{m_2}$  have been calculated

<sup>4</sup> Hepburn, *J. Chem. Soc.*, 1932, 550.

from the data of Harned<sup>5</sup> for the above solutions; for sodium perchlorate-acid solutions the data of Bates and Urmston<sup>6</sup> were employed, and for sodium dithionate-acid solutions that of Murdoch and Barton.<sup>7</sup> In all cases it was found that the value of  $(\partial \log f_2 / \partial m_1)_{m_2}$  was small, and that the second term on the right-hand side of (10) may be neglected with only a small error. In one case, for example the first term was of the order  $0.1 \times 10^{10}$ , while the second was  $0.001 \times 10^{10}$ . The values of  $(\partial \log f_2 / \partial m_1)_{m_2}$  have, therefore, not been tabulated. The surface concentrations given in the table are smoothed values obtained by plotting the calculated values against the salt concentration; they are given in moles/sq.cm.  $\times 10^{10}$ .

In all cases the amount of water adsorbed is reduced by the presence of acid, and by an increase in the concentration of the last. The thickness of the adsorbed layer in Å. may be obtained by multiplying the tabulated values of  $\Gamma_2$  by the molecular weight of water. The area occupied per molecule in the layer, assuming it to be unimolecular, is given by  $1/\Gamma_2 N$ .

Table III. gives the ratio of the area per molecule of water in the surface of solutions containing salt of concentration  $3M$  ( $A_0$ ) to that for salt solutions of the same concentration containing acid ( $A_s$ ). The values of  $\Gamma_2$  for sodium perchlorate and for sodium dithionate solutions have not been calculated because of the lack of reliable vapour pressure data, but the value of  $A_0/A_s$  is given. These figures also give the factor by which the thickness of the adsorbed water layer is reduced by the addition of acid. Table III. also gives the area in Å<sup>2</sup> occupied per molecule of water in the surface for a number of acid-salt mixtures of salt concentration  $3M$ . The area occupied per molecule of water corresponding to an adsorption of  $20 \times 10^{-10}$  moles/sq. cm., which is the value found for some of the more dilute solutions, is  $8.25 \text{ Å}^2$ ; the area of cross-section of a water molecule is of the order  $7 \text{ Å}^2$ , and the adsorption corresponding to this area, that is to a saturated unimolecular layer, is  $23 \times 10^{-10}$  moles/sq. cm.

### Summary.

The surface tensions of aqueous solutions of lithium chloride, calcium chloride, strontium chloride, barium chloride, sodium perchlorate and sodium dithionate, and of ternary solutions of these salts and  $0.1M$  hydrochloric acid have been measured by the maximum bubble pressure method. The presence of the acid produces a lowering of the surface tension, the effect increasing with increasing salt concentration. The amount of water adsorbed at the surface of the ternary solutions has been calculated from the Gibbs equation.

# THE ELECTRODEPOSITION OF SHEET CHROMIUM.

BY R. H. ROBERTS.

*Received 15th October, 1936.*

In connection with some work on the electrolytic passivation of metals, the need arose for some plates of pure chromium of sufficient thickness to permit of prolonged dissolution of the metal. Adcock<sup>1</sup> has succeeded in preparing large quantities of the metal in a high degree of purity; his product however was apparently in the form of irregular fragments which would require melting in a controlled atmosphere before they could be reduced to a form suitable for electrodes. He describes a high frequency induction furnace which served admirably for this purpose, but since such apparatus was not available in this laboratory an attempt had to be made to prepare thick, coherent layers of metal by direct electrodeposition.

A search of the literature for the most suitable composition of plating bath revealed that whilst there is general agreement regarding the optimum concentration of chromic anhydride, opinions differ widely as regards temperature, current density, and the quantity and nature of additional electrolytes, among which sulphuric acid, chromic sulphate, sodium sulphate and even acetic acid have received attention. Preliminary experiments seemed only to support this uncertainty since variation in concentration of sulphate or, within reason, of sulphuric acid had very little effect on the nature of the deposit. The temperature, however, should not be below 40° or above 50° C.

Where, as here, the primary requirement is thickness of deposit with uniformity of surface, the shape of the cathode has been found to be of fundamental importance. It was soon evident that any cathode approaching the form of a flat plate was quite impracticable, as nearly all the chromium was deposited as nodular excrescences at the edges and, in particular, at the corners of the cathode; even the amount of inequality of curvature involved in a cathode of elliptical section (e.g. a partially flattened tube) was found to be sufficient to cause preferential deposition, generally of an irregular nature, on the areas of greatest curvature. This variability of thickness of deposit was emphasised at higher current densities. With the ideal shape of electrode high currents are to be avoided on account of the nodular growths encouraged under such conditions; on the other hand a limit is set to the minimum current which may be employed by a sharp fall in efficiency of deposition. A value of 12.5 amps. per dcm.<sup>2</sup> was found to be most satisfactory.

With these points in mind cathodes of brass and bronze were constructed to the form of hollow cylinders with the lower ends turned to hemispherical shape. One of these was arranged in the bath to rotate about a vertical axis. The outer surface, on which the chromium was to be deposited, was of course highly polished before immersion.

Further details are probably best illustrated by the following data referring to one typical run.

<sup>1</sup> Adcock, *J. Iron and Steel Inst.*, 1927, 118, 369.

Cathode : Brass cylinder 1.28 cm. diam. terminated by a hemisphere, immersed to a depth of 5.2 cm. (Area immersed 21 cm.<sup>2</sup>).

Speed of rotation : 60 r.p.m.

Anodes : Two lead sheets, 1.3 cm. wide, immersed, on opposite sides of cathode, to a depth of 4 cm.

Bath : 250 g. CrO<sub>3</sub> (pure), 3 g. Cr<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> (anhydrous), water to 1 litre.

Temperature : 42° C.

Current strength : 2.2 amp.

Time of electrolysis : 7 days (168 hours).

Weight of metal deposited : 16.025 g.

Thickness of deposit (by micrometer) : At top of cylinder, 1.04 mm., at bottom, 0.87 mm.

This represents an efficiency of deposition of 13.4 per cent. assuming six faradays per gram-atom of metal.

The surface of the chromium was uniformly of a bright "satin" type, except for a few (in this instance, ten) small nodules, none more than two millimetres in diameter, which had the appearance of having been produced by prolonged adherence of gas bubbles at those particular points.

It must be admitted that the time of deposition is long and the current efficiency not good ; for the purpose of the work in hand, however, these considerations were of minor importance.

To remove the metal from the cathode, slots were milled through the chromium by means of a high speed carborundum wheel and the basis metal was dissolved away in nitric acid. The curved plates so formed were hard and brittle ; they could, however, be softened by heating in hydrogen to 1600 or 1700° C. The hydrogen was subsequently removed by evacuation at 900°.

## REMARKS ON THE INCORPORATION OF THERMODYNAMIC VARIABLES IN CHEMICAL KINETICS.

By E. A. MOELWYN-HUGHES (*Messel Research Fellow of the Royal Society*).

*Received 29th July, 1936.*

Arrhenius's conception of an energy of activation, the first point of contact between thermodynamics and chemical kinetics, is based on analogy between van't Hoff's expression for the temperature variation of a chemical equilibrium constant, namely,

$$\frac{d \ln K}{dT} = \frac{Q}{RT^2} \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (1)$$

and Arrhenius's relation for the temperature variation of a velocity constant, namely,

$$\frac{d \ln k}{dT} = \frac{A}{RT^2} \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (2)$$

Subsequent theoretical developments have been concerned with the nature of the equilibrium which, according to Arrhenius, exists between

passive and active molecules. Arrhenius himself, regarding  $A$  as independent of temperature, wrote

$$\ln k = \ln B - \frac{A}{RT} \quad (3)$$

The thermal change,  $Q$ , which accompanies a chemical reaction is, however, in general a function of temperature. Consistency with the kinetic relation

$$K = \frac{k_2}{k_1} \quad (4)$$

suggests the desirability of expressing  $A$  also as a function of temperature, and accounts for the many early attempts made in this direction.

### Experimental Approaches to the Study of Intermediate Complexes.

When, as it is not infrequently found, the kinetic order of chemical change does not coincide with, but is lower than, the stoichiometric order, the observed velocity constant must be a composite quantity, involving either simultaneous or consecutive changes, so that the Arrhenius equation can no longer have the relatively simple meaning which it has for elementary processes. The idea of an intermediate complex, possessing chemical individuality in addition to the physical peculiarity postulated by Arrhenius, emerged from the attempt to reconcile chemical complications with kinetical simplicity. Attempts, which we shall now illustrate, to extricate a single rate-determining step have led to the idea of an intermediate complex in connection with two distinct sets of phenomena.<sup>1</sup> The potential reactants, A and B, are supposed not to undergo measurable chemical change directly but first to establish a state of equilibrium:—

The measurable rate is assumed to be that of the decomposition of the complex, AB,

hence 
$$+ \frac{d[C]}{dt} = k_3[AB] = k_3K[A][B]$$

and since 
$$k_{\text{obs.}} = \frac{1}{[A][B]} \cdot \frac{d[C]}{dt} \quad (7)$$

we have 
$$k_{\text{obs.}} = k_3K \quad (8)$$

If C or D is identical with either A or B, the mechanism is catalytic. Michaelis (1913) applied this form of the intermediate-complex theory to the case where A is an enzyme and B is the substrate which it decomposes. Bjerrum and Brønsted (1923) independently applied the same principle to the case where A and B are both ions. Generally,  $K$  must be expressed in terms of activities rather than concentrations (G. N. Lewis, 1907; Debye and Hückel, 1922). Hence the  $K$  values of

<sup>1</sup> For a review, see Moelwyn-Hughes, *The Kinetics of Reactions in Solution*, p. 139, Oxford, 1933.

equations 5 and 8 must be multiplied by a factor  $f$ , which in this case is related to the separate activity coefficients by the equation

$$f = \frac{f_{AB}}{f_A f_B} \quad (9)$$

Combining with equation (8), we may write:—

$$\begin{aligned} (\text{Velocity at ordinary dilutions}) &= (\text{Velocity at infinite dilution}) \\ &\times \frac{f_{AB}}{f_A f_B} \quad (9a) \end{aligned}$$

Brönsted and Bjerrum differ in the choice of the rate-determining process, but the two views can be reconciled by adopting the stationary concentration hypothesis of Christiansen (1923). The expression for the concentration of the intermediate complex, assumed to have reached a stationary value, is

$$[AB]_{\text{stat.}} = \frac{k_2[A][B]}{k_1 + k_3} \quad (10)$$

*Ex hypothesi* the rate of reaction equals  $k_3[AB]_{\text{stat.}}$  so that

$$k_{\text{obs.}} = \frac{k_2 k_3}{k_1 + k_3} \quad (11)$$

When  $k_1 \gg k_3$ , there results the Brönsted condition

$$k_{\text{obs.}} \cong k_3 \cdot \frac{k_2}{k_1} \cong k_3 K \quad (12)$$

When  $k_1 \ll k_3$  there results the Bjerrum condition

$$k_{\text{obs.}} \cong k_2 \quad (13)$$

Empirical relations between velocity constants and equilibrium constants have also been discovered by Brönsted and Guggenheim, by Hammett (1928), and by Horiuti and Polanyi (1935). They signify a relation between energies of activation and heats of ionisation, and should prove helpful in ascribing energy levels to various intermediate complexes.

As the critical complex has only a transitory existence, our information concerning it is based on theoretical inference.

### Theoretical Approaches to the Study of Intermediate Complexes.

Theoretical approaches to the investigation of reactive complexes have been of two kinds: (1) We may select any molecule or pair of like or dissimilar molecules, and, making *ad hoc* postulates concerning its structure, we may construct the dynamical expressions which serve to describe its properties, among which chemical decomposition is one. (2) We may place full faith on equation (4), using an accurate expression for  $K$ , in thermodynamic or, preferably, statistical form. Then, armed with a fairly complete knowledge of what  $k_2$  means, we arrive at an expression for  $k_1$ , from which the required information about the complex emerges.

(1) F. Krüger<sup>2</sup> considers the relative probability that a labile atom in a polyatomic molecule may be found inside or outside a "sphere of action," while A. March<sup>3</sup> makes use of the idea that the complex may be dissociated or not, according as the generalised co-ordinates exceed

<sup>2</sup> *Gott. Nachr.*, 1908, 318.

<sup>3</sup> *Physikal. Z.*, 1917, 18, 53.

or are less than a certain limiting value. Dissociation or recombination is represented by the passage of the representative point in opposite directions through a critical area in phase space. Similar ideas have been much further developed by Pelzer and Wigner.<sup>6</sup> The simplest hypothetical picture of an active complex which has been presented is that of Goldschmidt,<sup>5</sup> who regards it as a normal molecule possessing an excess of kinetic energy.

(2) Efforts to study the intermediate complex by the second method have been much more numerous. As an example, we shall consider the theory of K. F. Herzfeld.<sup>6</sup> Using Stern's expression<sup>7</sup> for the dissociation constant of diatomic molecules, namely,

$$K = \frac{[AB]}{[A][B]} = h d^3 \left\{ \frac{8\pi}{kT} \left( \frac{1}{m_A} + \frac{1}{m_B} \right) \right\}^{\frac{1}{2}} (1 - e^{-h\nu/kT})^{-1} e^{-Q/RT} \quad (14)$$

and Trautz's expression for the rate of combination of atoms, assuming zero energy of activation, namely,

$$k_2 = s^3 \left\{ \frac{8\pi kT}{m_A} + \frac{1}{m_B} \right\}^{\frac{1}{2}} \quad . \quad . \quad . \quad (15)$$

Herzfeld obtains, by means of equation (4), the following expression for the velocity of dissociation

$$k_1 = \frac{k_2}{K} = \frac{kT}{h} \cdot \left( \frac{s}{d} \right)^3 (1 - e^{-h\nu/kT}) e^{-Q/RT} \quad . \quad . \quad . \quad (16)$$

If we identify the collision diameter ( $d$ ) with the equilibrium separation ( $s$ ) of the atoms in the molecule, the "steric" factor disappears, giving us

$$k_1 = \frac{kT}{h} \cdot (1 - e^{-h\nu/kT}) e^{-Q/RT} \quad . \quad . \quad . \quad (17)$$

Two special cases are of interest. When  $h\nu \ll kT$ ,

$$k_1 = \nu e^{-Q/RT}, \quad . \quad . \quad . \quad (18)$$

an equation which was arrived at on very different grounds by Rideal (1920), Dushman (1921) and McKeown (1923). When  $h\nu \gg kT$ , we have

$$k_1 = \frac{kT}{h} \cdot e^{-Q/RT}, \quad . \quad . \quad . \quad (19)$$

which is the simplified form in which Herzfeld applied his equation to numerical examples. Very similar considerations have been recently and independently advanced by Rodebush,<sup>8</sup> and Eyring (*vide infra*).

### Entropy of Activation.

The idea of an entropy of activation originates with van't Hoff, who, however, did not give it that name. Van't Hoff's treatment is as

<sup>6</sup> *Z. physikal. Chem.*, B, 1932, 15, 445; cf. *Annual Reports of the Chemical Society*, p. 94, 1936.

<sup>5</sup> *Physikal. Z.*, 1909, 10, 206.

<sup>7</sup> *Ibid.*, 1913, 44, 497.

<sup>8</sup> *Ann. Physik*, 1919, 59, 635.

<sup>9</sup> *J. Chem. Physics*, 1933, 1, 440.

follows.<sup>9</sup> Generally, we have  $d \ln K/dt = Q/RT^2$ , where  $Q$  is the heat of reaction. Since  $K = k_2/k_1$ ,

$$\frac{d \ln k_2}{dT} - \frac{d \ln k_1}{dT} = \frac{Q}{RT^2} \quad (20)$$

Now  $Q$  is usually a function of temperature; from Hess's equation, we obtain

$$Q_T = Q_0 + (C_2 - C_1)T \quad (21)$$

provided  $(C_2 - C_1)$  is independent of temperature. We then have

$$\frac{d \ln k_2}{dT} - \frac{d \ln k_1}{dT} = \frac{Q_0}{RT^2} + \frac{(C_2 - C_1)}{RT} \quad (22)$$

Neither the empirical validity of the Arrhenius equation

$$d \ln k/dT = A/RT^2,$$

nor that of the van't Hoff equation  $d \ln k/dT = A'/RT^2 + B$  permits of a resolution of the more complicated equation. Subsequent developments have, however, resulted from the dexterous splitting up of equation (22) into two equations alleged to account separately for the two velocity constants. The resolution is intuitive, and may or may not be justified by its consequences. Let it be assumed that we can write  $Q_0 = Q_2 - Q_1$ , and that we can also write

$$\frac{d \ln k_2}{dT} = \frac{Q_2}{RT^2} + \frac{C_2}{RT} \quad (23)$$

and

$$\frac{d \ln k_1}{dT} = \frac{Q_1}{RT^2} + \frac{C_1}{RT} \quad (24)$$

Provided the heats of activation and the specific heats of reactants and products are independent of temperature, we can integrate, writing

$$\ln k_2 = \text{constant} + \frac{C_2}{R} \ln T - \frac{Q_2}{RT} \quad (25)$$

and

$$\ln k_1 = \text{constant} + \frac{C_1}{R} \ln T - \frac{Q_1}{RT} \quad (26)$$

Generally, however, neither of these assumptions is valid, so that the expressions for the separate velocity coefficients contain terms of the form  $\int \frac{dT}{T^2} C dT$ . It is in this form that the analogue of thermodynamic entropy appears in kinetic studies.<sup>10</sup>

Within recent years, Soper has drawn attention to the possibility of interpreting deviations from normal behaviour of bimolecular reaction in solution in terms of entropy changes. By normal reactions we mean those for which  $P$  in the expression  $k = ZPe^{-E_A/RT}$  has the order of magnitude unity;  $Z$  is the gas kinetic collision frequency. It is pointed out that the thermodynamic change in free energy accompanying a certain reaction in a series of solvents varies in the same direction as the observed Arrhenius  $A$  values for one of the reactions.<sup>11</sup> The possible

<sup>9</sup> *Vorlesungen über theoretische und physikalische Chemie*, Vol. I., p. 228, Braunschweig, 1901.

<sup>10</sup> Kohnstamm and Scheffer, *Verlag Akad. Wetensch. Amsterdam*, 1911, 19, 878; Trautz, *Z. physikal. Chem.*, 1910, 68, 637; *Z. Elektrochem.*, 1915, 25, 4.

<sup>11</sup> *Discussion on the Critical Increment*, p. 45, 1931; Chemical Society.

temperature variation of  $P$ , which must be roughly the same as that of the Arrhenius  $B$ , is later discussed,<sup>12</sup> along with an interesting suggestion that values of  $P$  differing greatly from unity may be associated with those reactions for which reactants and products have very different "polarities."<sup>13</sup> Notable exceptions to the principle are cited in the paper, and even more striking ones could be added. For example, the reaction  $\text{AsO}_3^{--} + \text{TeO}_4^{--} \rightarrow \text{AsO}_4^{--} + \text{TeO}_3^{--}$ , which is polarly symmetrical, has a  $P$  value of the order of  $10^{-5}$  instead of approximately unity as required by Soper's rule. We consider, however, that this difficulty has since been removed<sup>14</sup> by making a necessary allowance for the electrostatic contribution to the total free energy change. Although the principle may not yet be regarded as established, there are numerous reactions which conform to it. Quantitative application of the idea of entropy to explain anomalous reaction rates have been made in Soper's most recent work.<sup>15</sup> He considers substance 1 to be converted into substance 2 *via* the formation of a substance  $x$ . To each of these is ascribed a thermodynamic probability  $W_1$ ,  $W_2$  and  $W_x$ . The entropies,  $S_1$ ,  $S_2$  and  $S_x$  corresponding to the three states are obtained from the general relation  $S = R \ln W$  per gram-mole.  $W_x$  is clearly less than either  $W_1$  or  $W_2$ . Soper now assumes that the *rate* of conversion of the complex into products is proportional to

$$W_2/W_x = e^{\frac{S_2 - S_x}{R}},$$

and that the rate of reversion of the complex into reactants is similarly proportional to  $W_1/W_x = e^{\frac{S_1 - S_x}{R}}$ . The relative probability of the reaction going forward from 1 to 2 is accordingly

$$\frac{e^{\frac{S_2 - S_x}{R}}}{e^{\frac{S_2 - S_x}{R}} + e^{\frac{S_1 - S_x}{R}}} = \frac{e^{S_2/R}}{e^{S_2/R} + e^{S_1/R}} \quad (27)$$

giving, for the rate of reaction

$$k_1 = \text{constant} \times e^{\frac{H_1 - H_2}{RT}} \times \frac{e^{S_2/R}}{e^{S_2/R} + e^{S_1/R}} \quad (28)$$

Similar expressions hold for the "break-up factor," and the rate of the reverse reaction; the ratio of the rate constants give an equilibrium constant of correct thermodynamic form. In equation (28), when  $S_2 > S_1$ , the break-up factor approaches unity; when  $S_2 < S_1$ , we have

$$k_1 = \text{constant} \times e^{\frac{H_1 - H_2}{RT}} \times e^{-S_1/R} \quad (29)$$

of which the last term may be as small as we please. Omitting the arsenite-tellurate reaction (discussed above) Soper's numerical results, at least as far as bimolecular reactions in solution are concerned, can claim considerable experimental support.

<sup>12</sup> Soper and Williams, *Proc. Roy. Soc., A*, 1933, 140, 59; see also Garner, *Phil. Mag.*, 1925, 49, 463.

<sup>13</sup> Roberts and Soper, *ibid.*, 1932, 140, 71.

<sup>14</sup> Moelwyn-Hughes, *Proc. Roy. Soc., A*, 1936, 155, 308.

<sup>15</sup> *J.C.S.*, 1935, 1393.

In this connection, the variation with temperature of the Arrhenius energy of activation,  $E_A$ , is of some importance. To ascribe numerical values to the entropy of activation from experimental values of  $\frac{dE_A}{dT}$  is a somewhat precarious task, because the effect may be due to a number of causes not necessarily related to entropy of activation. An apparent value of  $\frac{dE_A}{dT}$  may be due to; (1) The limitations of accuracy in the technique adopted for measuring  $k$ , (2) Inaccuracy in the control of temperature, (3) Occurrence of side reactions.

As examples we may quote (1) *The Decomposition of Acetone-dicarboxylic Acid*. Wiig's manometric data (1928) give  $E_A = 23,350 \pm 250$  calories. His titration data (1930) give  $E_A = 23,200 \pm 500$  calories. These are reasonable limits of accuracy for this technique (Moelwyn-Hughes and Hinshelwood, 1931), hence on the evidence available,  $\frac{dE_A}{dT} = 0$  (*Kinetics of Reactions in Solution*, Chapter II., 1933). (2) *The Decomposition of Diacetone-alcohol, Catalysed by Hydroxyl Ion*. At 25° C., Murphy (1931) found  $E_A = 17,040$ , and at 30° C.,  $E_A = 18,098$ . Hence the apparent value of  $\left(\frac{dE_A}{dT}\right)_{27.5^\circ\text{C.}}$  is + 211 calories/degree. La Mer and (Miss) M. L. Miller (1935) find  $E_A = 17,250$  at 24.9° C., and  $E_A = 17,240$  at 30°, hence  $\left(\frac{dE_A}{dT}\right)_{27.5^\circ\text{C.}} = -2$  calories, i.e., virtually zero. (3) The reaction between sodium thiosulphate and sodium bromopropionate. La Mer<sup>16</sup> records a high positive value for  $\frac{dE_A}{dT}$ . Dawson (1934) and Moelwyn-Hughes (1933) have independently stressed the necessity of allowing for side reactions in this case. Nielsen<sup>17</sup> acting on the suggestion, finds that the correction removes the so-called anomalous salt effect. It is not improbable that the value of  $\frac{dE_A}{dT}$  may also be radically altered by introducing the same correction.

These instances have been discussed from a somewhat different angle by La Mer.<sup>18</sup>

The least ambiguous case known of a genuine value of  $\frac{dE_A}{dT}$  is the inversion of cane sugar.<sup>19</sup>

### The Frequency of Binary Collisions in Solution.

The subject of chemical kinetics entered an important phase with the appearance of a well-known paper by Eyring and Polanyi in 1931. Within the last year, both authors have independently and almost simultaneously elaborated their theory to cover the case of bimolecular reactions in solutions.<sup>20</sup> There is agreement among these authors that the frequency of binary collision in solution is of a higher order of magnitude (being about 100 times greater) than the corresponding frequency for gaseous systems. Since this conclusion differs from an earlier one

<sup>16</sup> *J. Amer. Chem. Soc.*, 1933, 55, 1739.

<sup>17</sup> *Ibid.*, 1935, 58, 206.

<sup>18</sup> *J. Chem. Physics*, 1933, 1, 289.

<sup>19</sup> Moelwyn-Hughes, *Trans. Faraday Soc.*, 1928; *Z. physikal. Chem.*, 1934.

<sup>20</sup> Wynne-Jones and Eyring, *J. Chem. Physics*, 1935, 3, 492; M. G. Evans and Polanyi, *Trans. Faraday Soc.*, 1935, 31, 875.

which, though provisional, has been fairly widely accepted, we shall consider the evidence upon which it rests.

According to Wynne-Jones, Eyring, Evans and Polanyi, the velocity constant ( $k_2$ ) of a bimolecular reaction equals the product of the equilibrium constant ( $K^*$ ) which governs the formation of the active complex, and a frequency term  $\gamma$ . According to Wynne-Jones and Eyring,  $\gamma = kT/h$ ; according to Evans and Polanyi,  $\gamma = \frac{1}{2}v$ . In either case, it is supposed not to be markedly influenced by a solvent. Hence, in any system;

$$k_2 = K^* \gamma \quad . \quad . \quad . \quad (30)$$

The equilibrium constant in any dilute system is

$$K^* = \frac{c_{AB}}{c_A \times c_B} \quad . \quad . \quad . \quad (31)$$

Now if Henry's law is obeyed by all three solutes, we have

$$s = c_{\text{solution}}/c_{\text{gas}} \quad . \quad . \quad . \quad (32)$$

where  $s$  is the solubility, and

$$K^*_{\text{solution}} = K^*_{\text{gas}} \times \frac{s_{AB}}{s_A \times s_B} \quad . \quad . \quad . \quad (33)$$

which is the familiar equation of van't Hoff.<sup>21</sup> The similarity with equation (9a) is obvious. Since  $\gamma$  is taken as independent of the medium,

$$k_{2(\text{solution})} = k_{2(\text{gas})} \times \frac{s_{AB}}{s_A \times s_B} \quad . \quad . \quad . \quad (34)$$

Now, it appears that  $s$  has the order of magnitude 1/100 for a number of solutes in different solvents.<sup>22</sup> If, therefore, the "solubility of the transition state" is assumed to have this value, and if the energy of activation is the same in the two systems, it may be concluded that

$$Z_{(\text{solution})} = Z_{(\text{gas})} \times \text{about } 100 \quad . \quad . \quad . \quad (35)$$

The conclusion is thus based on a number of postulates, including one which invests the reactive complex with a definite solubility. The solubility of a reactive complex, though perhaps conceivable, is not measurable. The conclusion summarised in equation (35) must therefore always rest on purely theoretical foundations.

The earlier observation, to which reference was made above, was based on the experimental comparison of the observed velocities and energies of activation of those bimolecular reactions which have been measured in the gas phase and in solution. Such a comparison suggests that the frequency of binary collisions in the two dilute systems has the same order of magnitude.<sup>23</sup>

Choice between the two views will hardly be possible until more extensive applications of both have been tried out. In the meantime, it is a matter of convenience to place side by side the various evidences advanced in their favour.

**A Proposed Method of Determining the Entropy of Activation.**

Eyring<sup>24</sup> deduced the following formula for the velocity coefficient of chemical reactions of any order:—

$$\text{Velocity constant} = \frac{kT}{h} \cdot K^* \quad . \quad . \quad . \quad (36)$$

$K^*$  is a specially defined equilibrium constant, which, for systems undergoing simple motions, can be readily expressed in terms of partition functions. Eyring's general equation, which has proved a stimulus to thought on the subject of reaction kinetics, is particularly attractive in virtue of its generality.<sup>25</sup> It may be regarded as a generalisation of Herzfeld's velocity equation (16), in the same sense as Fowler's equilibrium equation<sup>26</sup> is a generalisation of Stern's equation (14). On applying equation (36) to the case of bimolecular reactions, Eyring shows (p. 114 of his paper) that the resulting expression reduces to the familiar classical expression, as, of course, it should be if equation (36) is at all general. It is true that the classical result emerges only after certain postulates are made, but these are no more severe than the postulates which underlie the derivation of the general equation (36). Accordingly, Eyring's quantum treatment and the old classical treatment may be regarded as harmonious and complementary.<sup>27</sup>

The application of Eyring's general theory to the specific problem of bimolecular reactions in solution was undertaken by Wynne-Jones and Eyring,<sup>28</sup> who accept the velocity in the gaseous state as a standard. To relate this to the velocity in solution, Henry's law (equation 32) is introduced. This approach is based on reliable experimental foundations, and follows, as we have seen, the scheme proposed by van't Hoff. The complexity of the dissolved state of matter makes it expedient to replace statistical partition functions by thermodynamic variables. The physical picture of the solvent effect is presented in two ways, *vis.* (1) union of solute and solvent molecules to form a larger active complex than is formed in the gas phase, or (2) the motion of the complex or of its constituent parts in a field of force different from that prevailing in the gas phase. "Either treatment simply has the effect of increasing the number of degrees of freedom" (p. 495). Here again, we are on fairly well-beaten tracks. "The rôle of the solvent in chemical kinetics has not yet been definitely correlated with any physical properties, and seems to belong to the category of specific chemical effects, which range from the formation of complexes, on the one hand, to an apparently inert or purely diluent influence on the other. The suggestion can therefore be made that the varying values of  $F$  (degrees of freedom) from solvent to solvent may indicate in a quasi-quantitative manner the extent to which the solvent enters into partnership with the reactant for purposes of decomposition."<sup>27</sup> A new principle which is employed by Wynne-Jones and Eyring may be enunciated as follows: the reactive complex resembles, or differs from, the products of reaction according as the entropy of activation,  $\Delta S^*$  (calculated from kinetic data by a method described below) resembles or is different from the entropy of reaction,  $\Delta S$  (calculated in the usual thermodynamic manner from experimental data on equilibrium constants). Their treatment of bimolecular

<sup>24</sup> *J. Chemical Physics*, 1935, 3, 107.

<sup>25</sup> *Cf. Annual Reports on the Progress of Chemistry*, p. 94, (1935).

<sup>26</sup> *Statistical Mechanics*, p. 106, Cambridge, 1929.

<sup>27</sup> Moelwyn-Hughes, *J.C.S.*, 1932, 106.

reactions is based on a quantitative comparison of  $\Delta S^*$  and  $\Delta S$ . Their method of calculating the entropy of activation,  $\Delta S^*$ , is as follows.

Omitting the transmission coefficient,  $\kappa$ , which is throughout the paper taken as unity, the theoretical expression proposed for the bimolecular velocity constant is

$$k_2 = K^* \cdot \frac{kT}{h} \quad (36)$$

$$\text{Substitution of } K^* = e^{-\Delta H^*/RT} \cdot e^{\Delta S^*/R} \quad (37)$$

$$\text{gives } k_2 = \frac{kT}{h} \cdot e^{-\Delta H^*/RT} \cdot e^{\Delta S^*/R} \quad (38)$$

An examination of the figures reproduced under  $\Delta H^*$  in Table II. (p. 499) makes it clear that  $\Delta H^*$  is identified with the Arrhenius energy of activation,  $E_A$ , hence the theoretical expression for the bimolecular velocity constant is

$$k_2 = \frac{kT}{h} \cdot e^{-E_A/RT} \cdot e^{\Delta S^*/R} \quad (39)$$

The units of entropy, we may infer from Table I. (p. 498), are calories per mole-degree, since Soper's figures, which are there reproduced, are known to be in these units. According to the classical theory, bimolecular reactions with normal velocities have coefficients given by the equation

$$k_2 = \frac{N_0}{1000} (r_1 + r_2)^2 \sqrt{\frac{8\pi kT}{\mu}} \cdot e^{-E_A/RT} \quad (40)$$

The units of  $k_2$  in equation (40) are litres, gram-molecules and seconds. Moreover, for molecules of ordinary masses and radii, the term

$$\frac{N_0}{1000} (r_1 + r_2)^2 \sqrt{\frac{8\pi kT}{\mu}}$$

is known to be about  $2 \times 10^{11}$  litres per gram-molecule-second. We thus have, for bimolecular reactions with normal velocities,

$$k_2 \cong 2 \times 10^{11} \times e^{-E_A/RT} \quad (40a)$$

At ordinary temperatures,  $kT/h$  is approximately  $6 \times 10^{13}$  seconds<sup>-1</sup>, hence the expression of Wynne-Jones and Eyring is

$$k_2 = 6 \times 10^{12} \times e^{\Delta S^*/R} \times e^{-E_A/RT} \quad (39a)$$

Eliminating  $k_2$  and  $E_A$  we have  $e^{\Delta S^*/R} = Z \cdot \frac{h}{kT} = \frac{2 \times 10^{11}}{6 \times 10^{13}}$  therefore  $\Delta S^* = -6.9$ . Hence Wynne-Jones and Eyring conclude (p. 499), that "when the reaction rate is just equal to that calculated by Moelwyn-Hughes (*i.e.*, calculated by equation (40)) the entropy of activation is seven units," and that "for a bimolecular reaction at 50-100° C. a kinetic theory collision diameter of 2Å. is equivalent to an entropy of activation of 6.9."

To take a numerical illustration of their theory, we shall apply it to a particular example—the union of triethylamine and ethyl bromide in benzene solution:  $(C_2H_5)_3N + CH_3Br \rightarrow (CH_3)_3N \cdot Br$ . The experimental results, in litres per gram-molecule-second, may be written in the form:

$$k_2 = 1.47 \times 10^8 \times e^{-11,190/RT}$$

Taking the experimental temperature as  $331^{\circ}$  Abs., and comparing with

$$k_s = \frac{kT}{h} \times e^{4S^*/R} \times e^{-11,190/RT}$$

it is found that  $\Delta S^* = -48.8$ .

If the theory of Wynne-Jones and Eyring is substantiated, it embodies a new principle, the importance of which has not hitherto been recognised, in that reacting systems differing as widely as the following, *vis.*,  $(\text{HI} + \text{HI})$ ,  $(\text{H}_2 + \text{Br})$ ,  $(\text{CH}_3\text{CHO})$  and  $(\text{NH}_4^+ + \text{CNO}^-)$  have all the same entropy of activation. The validity of the theory has, however, been challenged<sup>28</sup> and further defended.<sup>29</sup> The criticism draws attention to the dimensions and units of  $k_s$  in equation (39). The reply deals with the subtraction of certain constants which is necessary when  $\Delta S$  and  $\Delta S^*$  are compared, but to which no reference can be found in the original work. A recalculation of the published figures shows, however, that the constant in each case is zero. While this difference of opinion continues, the matter must be considered *sub judice*.

### The Influence of Pressure on the Kinetics of Reactions in Solution.

Fawcett, Gibson, Perrin and Williams<sup>30</sup> have recently studied the influence of high pressure on the velocity of numerous reactions in solution, which had previously been examined under ordinary conditions. Our experimental knowledge has thereby widened considerably from the somewhat narrow limits which formed the basis of our previous discussion of this subject.<sup>31</sup>

The general outline of the theory of the pressure effect has been given by van't Hoff,<sup>32</sup> whose treatment we shall here reproduce, using the newer notation of Lewis and Randall. Consider the equilibrium

We employ the two thermodynamic relations

$$\Delta F = -RT \ln K \quad . \quad . \quad . \quad (42)$$

$$\text{and} \quad \Delta F = \Delta E + P\Delta V - T\Delta S \quad . \quad . \quad . \quad (43)$$

$$\text{which give us} \quad \left( \frac{d \ln K}{dP} \right)_T = - \frac{\Delta V}{RT} \quad . \quad . \quad . \quad (44)$$

van't Hoff points out that this equation is in satisfactory agreement with results on the pressure-coefficient of the electromotive force of a reversible cell. Qualitatively, the principle may be stated as follows :

<sup>28</sup> Moelwyn-Hughes, *J. Chemical Physics*, 1936.

<sup>29</sup> Wynne-Jones and Eyring, *ibid.*, 1936.

<sup>30</sup> Fawcett and Gibson, *J.C.S.*, 1934, 386; Gibson, Fawcett and Perrin *Proc. Roy. Soc., A*, 1935, 180, 223; Williams, Perrin and Gibson, *ibid.*, 1936, 184, 684.

<sup>31</sup> *Kinetics of Reactions in Solution*, p. 256, 1933.

<sup>32</sup> *Vorlesungen über theoretische und physikalische Chemie*, 1, 236, Braunschweig, 1901.

a reaction which is associated by a decrease in volume (*i.e.*,  $\Delta V$  is negative) is favoured by an increase in pressure, and *vice versa*. So far, we are on purely thermodynamic grounds, limited by the provision that  $\Delta V$  does not depend on the pressure. We may go one stage further in the general argument. By definition

$$\Delta V = V_2 - V_1 \quad . \quad . \quad . \quad (45)$$

where  $V_1$  is the volume of the initial system, and  $V_2$  that of the final system. This equation may also be written as

$$\Delta V = (V_2 - V^*) - (V_1 - V^*) \quad . \quad . \quad . \quad (46)$$

in which  $V^*$  is an arbitrary volume. Combining with equations (41) and (44), we have

$$\left(\frac{d \ln k_2}{dP}\right)_T - \left(\frac{d \ln k_1}{dP}\right)_T = -\frac{(V^* - V_1)}{RT} + \frac{(V^* - V_2)}{RT} \quad . \quad (47)$$

The resolution of this equation into two separate ones, purporting to hold independently for the direct and reverse reactions, is again an assumption, which may or may not be vindicated by its consequences. The splitting up of equation (47) is equivalent to giving  $V^*$  an unique, as distinct from an arbitrary, value. Making the assumption, we obtain

$$\frac{d \ln k_2}{dP} = -\frac{(V^* - V_1)}{RT} \quad . \quad . \quad . \quad (48)$$

and

$$\frac{d \ln k_1}{dP} = -\frac{(V^* - V_2)}{RT} \quad . \quad . \quad . \quad (49)$$

These relations imply that the velocity  $k_2$  of chemical reaction increases on raising the pressure, provided the volume,  $V^*$ , of the active molecules (in the Arrhenius sense) is less than the volume,  $V_1$ , of the reactants. van't Hoff concluded that the data available to him were insufficient to test these equations.

Williams, Perrin and Gibson<sup>30</sup> find equation (49) to be obeyed in the case of the reaction between acetic anhydride and ethyl alcohol in toluene solution at 40° C., up to pressure exceeding 8000 kilograms per sq. cm. The agreement in the second example given by them (reaction between pyridine and ethyl iodide in acetone solution) is approximate only.

Just as the temperature coefficient of any velocity constant is best reflected by the (Arrhenius) energy of activation,  $E_A$ , the pressure coefficient is most conveniently shown by the volume change attending the conversion from normal to active molecules. In Table I. we give

TABLE I.

Reaction.	Solvent.	$(V^* - V_1)$ c.c. Per Gram-mol.
Hydrolysis of methyl acetate, catalysed by N . HCl	Water . .	— 9.0
Hydrolysis of sucrose, catalysed by N . HCl . .	Water . .	+ 2.7
Reaction between acetic anhydride and ethyl alcohol	Ethyl alcohol	— 16.5
" " "	Toluene . .	— 12.5
" " "	Hexane . .	— 4.16

the values for the volume increase ( $V^* - V_1$ ) calculated for certain reactions by means of equation (49). The velocity constant and pressure data for the first two reactions are cited by van't Hoff;<sup>22</sup> the corresponding figures for the remaining reactions are those recently determined by Fawcett, Gibson, Perrin and Williams.

It is now a matter of interest to study these figures in the light of the molecular statistics of the various reactions. Which of them we regard as fast or slow, depends, of course, on the collision frequency which we consider appropriate. If we accept the conclusions of Evans and Polanyi,<sup>22</sup> the hydrolysis of sucrose may be regarded as having a normal rate, the others exhibiting varying degrees of slowness. If we accept the gas kinetic value, or, at least, a figure of that order of magnitude, the hydrolysis of sucrose must be regarded as rapid,<sup>23</sup> the hydrolysis of methyl acetate as slow,<sup>24</sup> and the reaction between acetic anhydride and ethyl alcohol also as slow.<sup>25</sup> Gibson, Fawcett and Perrin<sup>30</sup> noted that the velocity of the slow reactions which they studied (adopting the gas-kinetic collision frequency as a standard) was increased by raising the pressure, and that a reaction with normal velocity (judged on the same basis) was much less influenced. We cannot reproduce ( $V^* - V_1$ ) for that reaction, because equation (49) is not obeyed. In view of these findings, particular interest attaches to the positive value of ( $V^* - V_1$ ) obtained from Röntgen's data for the velocity of the inversion reaction (Table I.). If we adhere to the same definition of normal velocity, we see that the only negative pressure coefficient hitherto recorded for a bimolecular reaction in solution refers to a reaction which is very fast.

A comparison of calculated rates with the experimental values found for the unimolecular decomposition of phenylbenzylmethylallylammonium bromide in chloroform solution showed the reaction to belong to the "fast" group.<sup>26</sup> Williams, Perrin and Gibson<sup>30</sup> find the coefficient  $dk_1/dP$  to be negative.

As far as the accurate, though not very extensive, evidence admits of a conclusion, it is that the van't Hoff relation (49) represents with fair accuracy the majority of the results. Moreover, bimolecular reactions which belong to the slow class have a positive coefficient  $dk/dP$ ; bimolecular and unimolecular reactions belonging to the fast class have a negative coefficient  $dk/dP$ . The two reactions belonging to the normal class which have been examined are these between ethyl iodide and sodium ethoxide, and between sodium chloracetate and sodium hydroxide. Upon these, the effect of pressure, though not zero, is very slight, e.g., a pressure of 3000 kilograms/sq. cm. roughly doubles the rate. In both cases, it must not be overlooked that some of the reacting ions are in equilibrium with the solvent, giving, for example, undissociated molecules of chloracetic acid and of sodium ethoxide. Since these are themselves capable of reacting, it is possible that the slight influence of pressure on the reacting system affects first the equilibrium constant, and alters the observed velocity indirectly.

Special mention must be made of the value ( $V^* - V_1$ ) = + 2.7 c.c. found from Röntgen's data on the inversion of cane sugar. In the first

<sup>22</sup> Moelwyn-Hughes, *Trans. Faraday Soc.*, 1929, 25, 81.

<sup>23</sup> Christiansen, *Z. physikal. Chem.*, 1924; 113, 35; Moelwyn-Hughes, *Phil. Mag.*, 1932, 14, 112.

<sup>24</sup> Moelwyn-Hughes and Hinshelwood, *J.C.S.*, 1932, 230; Moelwyn-Hughes and Rolfe, *ibid.*, p. 241.

<sup>25</sup> von Halban, *Ber.*, 1908, 41, 2417; Moelwyn-Hughes, *J.C.S.*, 1932, 95.

place, we note that, according to van't Hoff's theory, the volume,  $V^*$ , of the reactive complex must be greater than the combined volumes,  $V_1$ , of the hydrated sucrose molecule and the hydrated hydrogen ion. Structural organic chemistry has shown<sup>87</sup> that the reaction entails the opening of a furanose ring, and the subsequent closing of the chain-like structure into a pyranose ring. This conclusion is consistent with our deduction, and suggests that not only the reactive complex but the final products also may have a larger volume than the initial reactants. In the second place, we estimate the total dilatometric change in volume  $\Delta V = (V_2 - V_1)$  accompanying the inversion of one gram-molecule of sucrose in a 20 per cent. solution at 15° C. to be + 1.9 c.c. (Data of Fresenius in Landolt-Börnstein's Tables.) By equation (46), we have  $(V^* - V_2) = + 0.8$  c.c. If equation (49) holds, the rate of the catalytic synthesis of sucrose must also be influenced by hydrostatic pressure—a circumstance which may partly account for the inadequacy of the ordinary methods of organic chemistry to accomplish this synthesis.

### A Reformulation of the Methods of Introducing Thermodynamic Variables into Expressions for Reaction Velocity Constants.

As a starting-point we have to select the most plausible assumption from the large number that have been made. We shall assume, with most investigators, that the velocity of reaction is proportional to the number of molecules or of complexes for which the (Helmholtz) free energy,  $F$ , has reached a certain critical value. Hence, by analogy with equation (42),

$$k = \text{constant} \times e^{-\Delta F^*/RT} \quad (50)$$

Introducing equation (43), we obtain the relation

$$k = \text{constant} \times e^{-\Delta F^*/RT} \cdot e^{-P\Delta V^*/RT} \cdot e^{\Delta S^*/R} \quad (51)$$

where  $\Delta$  denotes the difference between the property for the passive and active molecules. Applying this relation to the case of bimolecular reactions, we shall accept the view advanced by Rodebush that the undetermined constant of equation (51), multiplied by a term  $e^{\Delta S_1^*/R}$ , represents the thermodynamic equivalent of the collision frequency. We then have

$$k_2 = Z_2 e^{-\Delta F^*/RT} \cdot e^{-P\Delta V^*/RT} \cdot e^{\Delta S_1^*/R} \quad (52)$$

$\Delta S_1^*$  is the remaining fraction of the entropy change. This step differs fundamentally from that taken by Wynne-Jones and Eyring. Our knowledge of the increase,  $\Delta E^*$ , in internal energy associated with the change from ordinary to activated molecules, is derived, as Arrhenius showed, from the temperature variation of  $k_2$ . Similarly, our knowledge of the increase,  $\Delta V^*$ , in volume associated with the same change, is derived, as van't Hoff showed, from the pressure variation of  $k_2$ . By elimination, it should be possible to learn something of the product  $Z_2 e^{\Delta S_1^*/R}$ , and by induction, to ascribe a value, if not a meaning, to the "entropy of activation,"  $\Delta S_2^*$ . Equation (52) gives directly van't Hoff's equation for the influence of pressure on the reaction velocity (equations 48 and 49); when  $\Delta V^*$  is zero, we have an equation of the form proposed by Soper (equation 28), and elaborated by La Mer. Equation (52) differs from that of Wynne-Jones and Eyring in that they use the

<sup>87</sup> Haworth, *Constitution of the Sugars*, 1929; Armstrong and Armstrong, *The Glycosides*, 1935.

frequency  $kT/h$  instead of the collision frequency  $Z_2$ ; in other words, their evaluation of what we have termed ( $\text{constant} \times e^{4S_1^*}$ ) differs from that of Rodebush, and from that given in Eyring's general theory.

Let us now consider a case of symmetrical equilibrium,<sup>38</sup> such as exists between  $\alpha$ -glucose and  $\beta$ -glucose in water. The heat effect is too small to be detected by ordinary calorimetric methods; the equilibrium constant,  $K$ , is unaffected by temperature and, to the best of our knowledge, the volume change is zero, i.e.,  $\Delta V = V_\beta - V_\alpha = 0$ . Accordingly, pressure should have no effect on equilibria of this kind. Experiments have not yet, however, been directed to test this conclusion of van't Hoff's<sup>39</sup> "*Bei Reaktionen ohne Volumenänderung fiel also diese Faktor  $[P\Delta V]$  weg und so wäre auch hier die gegenseitige Verwandelung von optischen Isomeren z.B. der theoretisch einfache Fall*" (p. 237).<sup>32</sup> At atmospheric pressure, the significance of the kinetics of these simple reactions has not been overlooked. They all have velocities equal to those given by the expression

$$k_2 = Z_2 \cdot e^{-E_A/RT} \quad (53)$$

in which  $E_A$  is the Arrhenius energy of activation and  $Z_2$  is the gas-kinetic collision frequency.<sup>40</sup> From equation (52), it follows that  $\Delta S_2^*$  for these reactions is zero. According, however, to the theory of Wynne-Jones and Eyring, "where the reaction rate is just equal to that calculated by Moelwyn-Hughes (i.e., by equation (53)) the entropy of activation is seven units" (i.e., seven calories per gram-molecule per degree). As mentioned above, we have no information about the volume change  $\Delta V^*$  in these cases. Should experimental work on the pressure effect confirm van't Hoff's view, we may conclude from equations (52) and (53) that  $\Delta E^* = E_A$ , i.e., the Arrhenius energy of activation for these reactions gives a direct measure of the increase in internal energy associated with the conversion from normal to active states. An assumption of this nature has, of course, underlain all attempts at determining the absolute rate of reactions in solution. In questioning the validity of the Arrhenius assumption, La Mer has omitted all reference to isomeric reactions.

Let us finally re-examine the pressure effect in the light of equation (52). Comparing it with the semi-empirical relation

$$k_2 = p \cdot Z_2 \cdot e^{-E_A/RT} \quad (54)$$

we obtain the relation

$$E_A = \Delta E^* + P\Delta V^* \left\{ 1 - T \left( \frac{d \ln \Delta V^*}{dT} \right)_P - T \left( \frac{d \ln P}{dT} \right)_P \right\} \quad (55)$$

<sup>38</sup> *Kinetics of Reaction in Solution*, Chapter V.

<sup>39</sup> Dr. Gibson explained to me some years ago the nature of the technical difficulties which it has not yet been possible to overcome.

<sup>40</sup> "Mutarotation of Glucose in Water," Moelwyn-Hughes, *Phil. Mag.*, 1932, 14, 112; "Mutarotation of Beryllium Benzoylcampbor in Carbon Tetrachloride Solution," Lowry and Traill, *Proc. Roy. Soc. A*, 1931, 132, 398; Traill, *Phil. Mag.*, 1932, 14, 225; "Beckmann transformation of Benzophenoneoxime Picryl Ether," A. W. Chapman, *J.C.S.*, 1934, 1550; *ibid.*, 1935, 1223; "Mutarotation of Glucose in Heavy Water," Moelwyn-Hughes, Bach and Bonhöffer, *Z. physikal. Chem.*, A, 1934, 469, 113; Moelwyn-Hughes, *ibid.*, B, 1934, 26, 272.

<sup>41</sup> Hildebrand, *Solubility*, 1924, p. 102 1st Ed.

$T\left(\frac{dP}{dT}\right)_P$  may be identified with the internal pressure,<sup>41</sup> hence

$$E_A = \Delta E^* + P\Delta V^* \left\{ 1 - T \left( \frac{d \ln \Delta V^*}{dT} \right)_P \right\} - \pi \Delta V^* \quad (56)$$

The internal pressure for pure acetone is about  $5.8 \times 10^9$  dynes/cm.<sup>2</sup>, and for ethyl alcohol about  $13 \times 10^9$ . A hydrostatic pressure of 3000 kilograms per sq. cm. is  $2.94 \times 10^9$ , so that under high pressure conditions  $\pi$  and  $P$  are commensurate. Whether the Arrhenius energy of activation,  $E_A$ , increases or decreases as the pressure is raised depends on the sign of the volume increase,  $\Delta V^*$ , and on the sign of the term inside the bracket. Unfortunately,  $\left(\frac{dV^*}{dT}\right)_P$  is not known, but the variation with temperature (without the restriction of constant pressure)

of van't Hoff's  $\Delta V^*$  may be found from experimental data. They are shown in Table II. It is of interest to observe that for these two reactions the term within the brackets has opposite signs; so also has the experimental coefficient  $dE_A/dP$ . The corresponding expression for  $p$  (equation 54) can be readily obtained.<sup>42</sup> An attempt to determine either  $\Delta E^*$  or  $P$  numerically requires a knowledge of quantities which are not yet available, as, for example, the value of  $\left(\frac{dP}{dT}\right)_P$  for the reacting

system (as distinct from the solvent), and the functional relationship of  $\pi$  to  $P$ .

The logical introduction of thermodynamic expressions into the study of reactions kinetics can thus yield information concerning properties of active molecules, other than the energies and volumes, with which Arrhenius and van't Hoff were primarily concerned.

# FORMATION OF DEHYDRATION NUCLEI ON CRYSTALS OF CHROME ALUM.

BY J. A. COOPER AND W. E. GARNER.

*Received 12th October, 1936.*

Nuclei formed on the surfaces of isotropic material are usually circular in shape, growth in this case being uniform in all directions along the surface. Where, however, there are marked divergences between the rates of growth for different directions in the crystal, the nuclei may possess a complex outline, as was found for  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ , where they are star-shaped on the surface of the (110) plane,<sup>1</sup> and <sup>2</sup> for  $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ , where they are elongated discs. The conditions under which nuclei form and grow in size have already been investigated <sup>1, 2</sup> in some detail for crystals of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  and  $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ , and in these cases it has been shown that there is an induction period before the nuclei become visible, and this has been ascribed to an abnormally slow rate of growth of the nuclei when very small. It is possible that induction periods in solid reaction occur only when the nuclei possess a complex irregular shape, and not at all when the nuclei are spherical. This might be the case if the strains set up by uneven growth of the nuclei were responsible for the acceleration of the rate of nuclear growth. It was therefore important to carry out an investigation on some hydrate where the rates of growth in all directions were the same, and crystals of chrome alum have been chosen for this purpose.

## Experimental.

A saturated solution of Kahlbaum's "Puriss" Chrom Alum

was made in distilled water, and this was allowed to crystallise in an air thermostat under such conditions that the solutions were protected from dust. The surfaces of the crystals were very delicate, and it was found to be impossible to employ the method of drying adopted previously with copper sulphate for they become scratched under this treatment. Also, the method of draining used by Garner and Southon was found to be ineffective in this case. The method finally adopted was to remove the crystals from solution and place them for a very short time in distilled water (about 1 second) and then place one face of the crystal on soft filter paper. This ensured that drying occurred without scratching. So prepared, the crystals could be stored in a desiccator over powdered chrome alum for several weeks without decomposition occurring.

The vessel used for the study of nuclei formation was the same as that used previously. The crystals were exposed to a high vacuum, which is attained within a few seconds of applying the pump, and the nuclei formed are observed either visually or photographs are taken of them at suitable intervals of time. In most cases 15 to 20 photographs were taken during the course of a single experiment. Usually about 50 nuclei were formed within the field of vision of the cathetometer.

<sup>2</sup> Garner and Southon, *J.C.S.*, 1935, 1705.

### Experimental Results.

The nuclei are circular in shape, as would be expected for a cubical crystal (Fig. 1), but since the rate of growth into the interior is not so rapid as along the surface, due to retardation of the escape of water through the varying thicknesses of the dehydrated product, the nuclei actually consist of flattened half spheres. At an early stage in the growth of a nucleus, a cavity forms in its centre, and this is well shown in Fig. 1. The nuclei possess a diffuse and somewhat irregular edge, indicating that the area of the interface between the hydrate and its product is quite large. There are differences between the rates of growth in different directions along the surface, but these are, however, small and of the order of 2-4 per cent. The lack of uniformity in the growth suggests that there are discontinuities within the crystal lattice.

FIG. 2.

### Rates of Growth of Nuclei.

Measurements of the rates of growth made visually indicated that the nuclei grow abnormally slowly when small, and do not increase in size at a linear rate until they are above  $10^{-3}$  cm. in diameter. It was therefore decided to carry out measurements by the photographic method in order to measure accurately the changes in the rates of growth of the nuclei. About twenty exposures are taken of a dehydrating crystal at suitable intervals of time, and for each crystal, ten nuclei are chosen, and the diameters of these measured on each exposure. For each nucleus a plot

0.4 mm. diameter.

Magnification 3.

FIG. 1.

*[To face page 1740.]*

is made of the size against time and in order to obtain greater accuracy, the plots for the ten nuclei are combined in a composite curve. The origin of the nuclei on the time axis varies from case to case, and in order to obtain the composite graph it is assumed that the nuclei always require the same time to reach a particular size. The assumption appears to be justified both by the photographic and visual observations. Three composite curves are shown in Fig. 2, and it will be seen that the rate of growth is exponential at first, becoming linear above  $10^{-3}$  cm.

**Rate of Nucleus Formation.**—A number of measurements have been made at  $14^{\circ}$  C. of the increase in number of the nuclei with time. After an induction period of about 30 minutes, the increase in number was practically linear (Fig. 3 A), as was found previously for  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ . The behaviour is, however, in sharp contrast with that of nuclei on

FIG. 3.

where the number increases as the square of the time. The induction periods were not, however, very reproducible, so that no attempt was made to measure temperature coefficients.

It has been shown that the nuclei grow at a linear rate when above  $10^{-3}$  cm. in diameter, so that the size of any nucleus is a linear function of the time which has elapsed since it started to grow at a linear rate. Therefore, if the diameters of all of the nuclei be measured at any fixed time, as can be done from the photographs of the dehydrating crystal, and the number above a given size be plotted against size, a graph should be obtained of the same form as that obtained when plotting number against time. This is done in Fig. 3 B, and a linear relationship is seen to be obtained for the nuclei above  $10^{-3}$  cm. in size. This confirms the conclusion that the number of nuclei increases linearly with the time.

### Discussion.

The slow rate of growth of small nuclei as shown in Fig. 2 is of considerable importance for the interpretation of the nature of induction

periods in solid reactions, and it is therefore worth while considering the theoretical significance of these slow rates of growth.

A possible explanation of the phenomenon is that it is due to a negative tension set up in the interface by the tendency to contraction of the product. If this tension is constant, the problem may be treated thermodynamically, as was done by Kelvin to account for the change in vapour pressure with variation in the radii of small drops. For small drops,  $RT \log_e p/p_0 = 2MS/r\rho$ , where  $p$  is the vapour pressure of a drop of radius  $r$ ,  $p_0$  the ordinary vapour pressure, and  $M$  the molecular weight of the vapour,  $S$  the surface tension, and  $\rho$  the density of the liquid. In the case of a nucleus on the surface of a crystalline hydrate,

FIG. 4.

$p$  is the dissociation pressure of water vapour at the interface for a nucleus of radius  $r$ ,  $p_0$  the ordinary dissociation pressure for a plane surface and  $S$  the tension in the interface, and since  $M$ ,  $S$ ,  $T$ ,  $\rho$  and  $p_0$  are constants,

$$RT \log p = K_1/r + K_2,$$

which gives the variation of the dissociation pressure with curvature.

Now the rate of growth of the nuclei in hard vacuum is proportional to the rate of evaporation of water molecules from the interface, and since the latter is proportional to the dissociation pressure it follows that

$$RT \log dr/dt = K_1/r + K_2'$$

and the graph of  $\log_{10} dr/dt$  against  $1/r$  should give a straight line. Such plots are given in Fig. 4 for the nuclei observed on three films and

within the experimental error it will be seen that there is agreement with the thermodynamic argument. Three values of the slope  $k$  are obtained, — 2.83, — 2.37, —  $2.83 \times 10^{-2}$ , which give a mean value of

$$- 2.68 \times 10^{-2} \text{ cms.}$$

Since  $k = \frac{2mS}{2.303 RT \rho}$ , it is seen that  $S = 7.49 \times 10^6$  dynes/cm., which compared with the surface tension of water (75 dynes/cm.), is a very large tension. It would give rise to pressure differences in the case of the nuclei of the diameters on which the measurements were made of many tons per sq. in.

The thermodynamic relationship holds only over the curved portion of Fig. 2, and breaks down before the rate of growth becomes constant. It is, therefore, necessary to make the additional postulate that the tension ceases to be constant when the particles reach a certain size, and this may well be the case for the contraction of the material of the nuclei giving rise to the cavities and cracks visible in the photographs would cause a diminution of the tension. It is also necessary to assume that the nuclei originate at centres of disturbance which are much larger than molecular dimensions, otherwise it would be impossible to account for the observed lengths of the induction periods. All that can be said at the moment is that this thermodynamical argument is not incompatible with the results observed.

It can be tested further, for one requirement of the theory is that the dissociation pressure of a small nucleus should be less than that of a large nucleus. In which case, it should be possible to check the growth of small nuclei at lower vapour pressures than for large nuclei. Measurements are now being made to investigate this matter.

Tests have been made of the applicability of other equations, *viz.*,

- (1)  $dr/dt = k_1 - k_2 r$ , (2)  $dr/dt = k_1 - k_2/r^2$ ,  
 (3)  $dr/dt = kr^2/(r^2 + k)$ , (4)  $dr/dt = kr/(r + k)$ ,  
 (5)  $dr/dt = k_1 + k_2 r$  and (6)  $\log r = kt + \text{const.}$ ,

and except for (3) which gives a very good fit over the whole curve and (6), which gives a fit over the curved portion of Fig. 2 only, the equations are not in agreement with the experimental results. The agreement with equation (3) is, however, very good. It can be tested by means of the integrated form of this equation (3) giving the variation in  $r$  with time,

$$t = \frac{r^2 + Ar - B}{Cr}$$

and the values of  $t$  calculated in this way are compared with the experimental values in Table I.

This is the only equation we have found which is in agreement with the complete experimental curves.

It is, however, an empirical equation, and up to the present it has not been linked up with a physical explanation.

The rate of decomposition of certain solids which decompose with evolution of heat, *viz.*, mercury fulminate, barium azide, and potassium azide, changes very rapidly with the time. Thus for mercury ful-

minate the rate varies as the twentieth power of the time. It is not possible to account for these facts in terms of solid nuclei growing at a linear rate from the moment of origin, and it has been suggested previously either that the reactions are chain reactions, or that the nuclei when very small grow at an accelerating rate. It has not been found possible to decide between these two theories in the case of exothermic changes for no nuclei have been found in such cases which are susceptible of accurate measurement of their rates of growth. The above experiments with chrome alum do, however, show that the cause of the marked induction periods in these exothermic decompositions may lie in the lack of linearity in the rate of growth of small nuclei.

### Summary.

Measurements have been made of the rates of growth of the spherical nuclei formed on dehydration of crystals of chrome alum. The nuclei have been shown to grow at an accelerating rate up to  $10^{-3}$  cm., and then to increase in size at a linear rate. The causes underlying the accelerating rate of growth are, however, obscure. The presence of a tension in the interface depressing the dissociation pressure would, however, account for the results obtained, and on applying the Kelvin equation a value of  $7.49 \times 10^6$  dynes/cm. is obtained for the tension. The bearing of the results on the induction periods in solid reactions is discussed.

## ADSORPTION OF CARBON MONOXIDE ON ZINC OXIDE.

BY W. E. GARNER AND J. MAGGS.

*Received 23rd October, 1936.*

The adsorption processes occurring on porous bodies often require lengthy periods for the establishment of equilibrium. In the case of some metals and simple crystalline salts, the adsorption is separable into two processes, (1) an initial rapid process believed to occur on the readily accessible areas of the adsorbent, and (2) a slow process due to diffusion of the gas down capillaries of molecular size, the rate of which obeys the diffusion equations and is also proportional to the degree of saturation of the gas on the readily accessible areas.<sup>1</sup> The sharp separation into two processes is possible only for certain types of porous body. For precipitated oxides, for example, there is a tendency for the two processes to be merged into one, probably due to a continuous gradation in the size of the pores. In such cases, it is generally found that the diffusion equations do not hold exactly and that the deviations which occur from these equations are affected by conditions which modify the pore diameters, such as sintering, etc.

<sup>1</sup> Ward, *Proc. Roy. Soc., A*, 1931, 133, 522; Bradley, *Trans. Faraday Soc.*, 1934, 30, 587.

The occurrence of capillary flow makes the investigation of adsorption on porous bodies very difficult, especially when information is sought regarding the activation energy of such processes. Activation energies derived from rates of adsorption are always of doubtful value if capillary flow is present, for it is uncertain to what extent the activation energy is that of the adsorption process itself or that of surface flow.<sup>2</sup> It is therefore of interest to study the adsorption of gases under such conditions that complications due to capillary flow are at a minimum. Such conditions were observed during the adsorption of carbon monoxide and dioxide on a specimen of zinc oxide. It was found that the adsorption was practically instantaneous at room temperature and that the secondary slow adsorption was practically absent.<sup>3</sup> Experiments have been made with this oxide to determine if the adsorption processes, which give heats of adsorption 12-18 K. cal./mol., possess activation energies. With this purpose in view, the adsorption isobar was studied to find out whether or not a minimum was present.<sup>4</sup> In addition, it was sought to check the values for the heats of adsorption as determined in the thermocouple calorimeter.

### Experimental.

Carbon monoxide was prepared from formic acid and sulphuric acid and the zinc oxide used was that employed previously.<sup>3</sup> The oxide, which was in granular form, was contained in a platinum gauze cylinder suspended in the centre of the adsorption vessel by means of fine tungsten wire hooks sealed into glass. The weight of oxide was 2.21 gm. The adsorption vessel was connected through a liquid air trap to gas burettes, McLeod and Pirani gauges and high vacuum pumps. The volumes of various parts of the apparatus were determined with helium gas.

The oxide was baked out in a high vacuum at 460° C. for two hours before each experiment and after cooling to room temperature was placed in a bath kept at constant temperature. The temperatures ranged from that of liquid oxygen up to 40° C. When the adsorbent had attained a constant temperature, a known volume of carbon monoxide was admitted from the gas burettes, and readings taken of the pressure after five and twenty minutes respectively. Equilibrium was always attained within five minutes except for the lowest temperatures, provided that the oxide was in thermal equilibrium with the surroundings.

### Adsorption Isotherms.

The adsorption isotherms were determined by the admission of successive quantities of carbon monoxide. It was not found possible to control the baking out so as to ensure that the surface of the oxide was in exactly the same state for each experiment so that it was advantageous after each baking-out to make adsorption measurements at two temperatures. This was done in the determinations of the heats of adsorption between 0° and 20° C. Except at very low pressures and low temperatures, the plot of  $\log p$  against  $\log$  amount adsorbed gave a good straight line, so that the experimental results were in good agreement with Freundlich's equation. The results of two typical experiments are given in Fig. 1 for the oxidised and reduced zinc oxide respectively. The first two measurements in each experiment were made at 20° C., the next two at 0° C., the next at 20° C., and so on. The reduction of the oxide with

<sup>2</sup> Cf. Lennard-Jones, *Trans. Faraday Soc.*, 1932, **28**, 433.

hydrogen or its oxidation with oxygen had but a slight effect on the

FIG. 1.

amounts of gas adsorbed or on the heat of adsorption. Also, the presence or absence of mercury vapour was found to have but a slight effect on the nature of the results; the amount of gas adsorbed was greater in the absence of mercury vapour but the heats of

adsorption were unaffected.

### Heats of Adsorption.

The heats of adsorption were calculated from the adsorption isotherms with the aid of the Clausius-Clapeyron equation. Typical results for the untreated zinc oxide, reduced and oxidized zinc oxide are given in Table I. for the temperature interval 0-20° C. Mercury vapour was present in these cases in order that the results should be strictly comparable with those determined in the thermocouple calorimeter, where mercury vapour was also present.

It will be noted that the heats do not change appreciably with the amount of gas adsorbed.

The surface of the catalyst was as nearly as possible in the same state as that employed in measurements of the heats of adsorption in the thermocouple calorimeter and hence the above results should be directly comparable with those of Garner and Veal. The experimental heats varied with the amount of gas adsorbed, that is, with the gas pressure above the oxide. Between 0 and  $2 \times 10^{-3}$  cm. pressure,  $Q = 18.2$  and between 2 and  $8 \times 10^{-3}$  cm.  $Q = 12.5$  K. cal./mol. The heat of adsorption calculated by the thermodynamic method does not include that of the first small quantities adsorbed and these heats will therefore not be comparable with the first of the above values. The second, however, was determined within the same range of equilibrium pressures as the thermodynamic heats and the agreement is within the experimental error of the direct method.

### Heats of Adsorption at Lower Temperatures.

Two or three readings were made of the adsorption at 0° C. and these were followed by measurements to obtain the adsorption isotherm at some other fixed temperature. The conditions of baking out were kept as constant as possible but it was found necessary to make corrections to bring the curves to the same condition of the surface. The results obtained are given in Table II.

TABLE II.

—1'2	13'5	12'0	—	—
—1'3	—	12'4	—	—
—1'4	13'6	12'9	—	—

The heats of adsorption calculated from these values are given in Table III. It will be noted that in general the differential heats fall off as the amount adsorbed increases and as the temperature is lowered. The heats of adsorption between liquid air temperatures and 195° C. could not be derived with any accuracy from the results in Table II., and hence no conclusion can be drawn as to whether or not any part of the adsorption

at these temperatures occurs with heats of adsorption of the order of 0'5-2 K. cal./mol.

### Adsorption Iso-bar.

The adsorption isobar is given in Fig. 2 for pressures of  $10^{-3}$  cm. Hg for the range of temperatures 90-293° K. The curve for  $10^{-3}$  cm. Hg is

FIG. 2.

very similar in shape. There is no evidence that there is any change in the character of the adsorption between room and liquid air temperatures, except for a gradual decrease in the average heat of adsorption, and there is no discontinuity in the isobars, similar to those obtained by H. S. Taylor

and his co-workers, for many oxides. For example, H. S. Taylor and Strothers<sup>\*</sup> find a minimum at about 200° K. and also two maxima on the adsorption isobar of hydrogen on ZnO. The absence of a discontinuity in the case of carbon monoxide on zinc oxide supports the contention that such discontinuities do not occur in the absence of capillary flow. It is thus doubtful if conclusions drawn from minima on adsorption isobars with regard to the activation energy of adsorption processes are valid unless it has been proved that capillary flow is absent.

### Summary.

The heats of adsorption of carbon monoxide on zinc oxide have been determined from the adsorption isotherms over the range of temperatures 195-318° K. and are found to be in agreement with the results obtained in the thermocouple calorimeter.

The adsorption isobar shows no discontinuity and the conclusion is reached that the discontinuities are met with only in the case of adsorbents where capillary flow is present.

## REVIEWS OF BOOKS.

**Tables of Physical and Chemical Constants and some Mathematical Function.** By G. W. C. KAYE and I. H. LABY. Eighth edition. (London: Longmans, Green & Co. Ltd. Pp. 162. Price 14s.)

In the absence of Professor Laby in the antipodes Dr. Kaye has revised these well-known tables, bringing them up-to-date and revising any errors which have been noticed. These tables are too well known to need an extended review. Apart from the inclusion of many more recent values, there has been considerable re-writing in the section on thermometry.

**Die Fermente und ihre Wirkungen.** By C. OPPENHEIMER. Supplement, Lieferung 1 (Bd. I: Spezieller Teil: Hauptteil VII.-XV., Den Haag: W. Junk, Verlag, 1935. Pp. 160. Price 28s.).

The enormous, ever increasing mass of scientific knowledge makes it a difficult task to keep it, so to say, sweet and alive, and prevent it simply accumulating in the issues of periodicals belonging to the past. One has to be most thankful to those men and institutions who have the industry, the energy and the means to concentrate and correlate this wealth of fact and to spread its knowledge outside the narrow range of the pure specialists.

Professor Oppenheimer has become more and more the "Beilstein" of the science of enzymes. His text-book on this subject is so well known that nothing need be said about its value. The supplement which is

beginning to appear is meant to bring the special part of the original work up to date. This first issue treats the esterases (lipases, lecithases, tannases, phosphatases). It commences with a more general, important discussion of modern conceptions of enzyme structure which necessitate the use of a new terminology.

H. F.

**Electrolytic Oxidation and Reduction.** Monographs on Applied Chemistry, Vol. IX. By S. GLASSSTONE and A. HICKLING. (Pp. ix + 420. Chapman & Hall. 25s. net.)

To the works chemist who has never used electrolytic methods this book opens up new avenues and gives food for thought. The neat processes and the control one can exercise on the progress of the reactions once the fundamental principles are known should have a direct appeal.

To the research worker this book is invaluable, bringing forward as it does the principles of Electrolysis in the light of modern knowledge, thus making a notable addition to existing textbooks. It deals, from a laboratory point of view, equally well with fundamental principles as with experimental data, and the voluminous references enable one to follow any phase of the subject more closely should one so desire. Where conflicting views are held, the pros and cons of each are logically discussed. Conflicting experimental results are pulled into line with theory in such a capable manner that one immediately has confidence that in this work will be found first principles that will hold good.

To the careful reader, imagination will present possibilities of processes not given, because the effective manner in which the data is given for the suppression of undesirable compounds, will open up the way to the production of these compounds when they become desirable.

The title has an advantage and a disadvantage. In the first place it focusses the attention on the fact that in aqueous solution the chief reaction is the electrolysis of water and the chief products Oxygen and Hydrogen. In the second place, it leaves the uninitiated with the impression that these are the only possibilities of electrolysis, although an attempt has been made to remedy this impression by the inclusion of a chapter on substitution as secondary phenomena.

Altogether a well-written and readable book.

R. P. L. B.

**Corrosion Resistance of Metals and Alloys.** By ROBERT J. MCKAY and R. WORTHINGTON. Pp. 492. (New York: The Reinhold Publishing Corp. London: Chapman & Hall, Ltd. Price 35s. net.)

Mr. R. J. McKay's name has long been associated with the study and combating of corrosion. The present treatise, written in collaboration with Mr. R. Worthington, is assured, therefore, of a very wide welcome.

The first part ("General and Theoretical") is much shorter than and is frankly subservient to the second ("Corrosion Behaviour of Specific Metals and Alloys"). Whilst the author's unconventional treatment of theoretical matters leaves loopholes for criticism, the essential *raison d'être* of the work is represented by the "specific" second part. This

presentation in accessible and assimilable form of data concerning the behaviour of metallic systems in corroding media of various kinds should prove of considerable assistance to many technical workers.

The task of writing such a book is admittedly attended with much difficulty, not the least part of which is associated with the classification of the relevant data. After much consideration of alternatives in both sections, the authors adopt for the specific part a system whereby the information is arranged under the headings of the respective metal systems. Whilst the engineer may prefer to find the behaviour of materials discussed under the particular corroding medium with which he is concerned, any inconvenience is reduced to a minimum by an exceptionally thorough subject index, which constitutes a gratifying feature of the work. The length of the author index further reflects the wideness of the field surveyed.

The style may prove irksome to many, and there is much looseness of expression, as for example the rendering of corroding media indiscriminately as "corrodents," "corroders," and "corrosives," and stainless steel as "stainless." In all the tables and throughout the text corrosion rates are expressed as "mg. per sq. dm. per day," the reader being left to infer that this refers to loss in weight. Similarly, in Table IV, where factors are given for conversion to "inches per year" and "cm. per year," it is left to inference not only that these values represent depth of penetration (which is sufficiently obvious), but also that the total loss of weight is assumed to be distributed uniformly over the whole area of the specimen, an assumption that is frequently remote from the truth.

The treatment, in general, is thoroughly up-to-date; certain curious lapses have been noted, however. Thus, a brief account of the protection of magnesium and its industrial alloys includes no mention of the selenium process of Bengough and Whitby. A noteworthy omission from the metal systems is that of silver and its alloys which now find many important applications in chemical engineering. Sectional bibliographies at the end of each chapter, supplement usefully the information given in the text, and the number of references so included is extremely large. The production and printing is in every way satisfactory.

W. H. J. V.

**Coal: Its Constitution and Uses.** By W. A. BONE and G. W. HUMUS; with a chapter on fuel economy and heat transmission in industrial furnaces by R. J. SARJANT. Pp. vii + 631. (Longmans, Green & Co., 1936. 25s.)

During the eighteen years which have passed since Professor Bone's monograph on coal was published, there have been important developments in coal chemistry, and in the application of coal as an industrial raw material. The present book follows the same general lines as its predecessor, but the task of bringing all the material in it up to date has involved much more than mere revision, and many entirely new sections now appear.

The introductory chapters are concerned with the coal industry from the economic side, and are followed by a description of the geology of the coal measures, and the mechanism of changes in the series lignin—peat—

coal. The different systems of classification of coals are reviewed, with particular reference to microscopic examination of bituminous types. The chemical constitution of coal is then considered, as revealed by the three alternative methods of attack: thermal decomposition, solvent extraction and oxidation. The chemistry of coal combustion is discussed in connection with such problems as smoke abatement, firing of boilers, and the use of pulverised fuel. This order of treatment leads naturally to a series of chapters on the carbonisation of coal, together with an account of the manufacture of water-gas and the complete gasification of coal. Fuel problems connected with the iron and steel industries are next examined, and the use of coal for power production, and for domestic heating, is considered in subsequent sections. A description of the recently established coal hydrogenation process is included and the phenomena of surface combustion are also reviewed. The final chapter, contributed by Dr. Sarjant, is concerned with fuel economy and heat transfer in industrial furnaces.

The book should appeal to a wide range of readers, in both academic and industrial circles, as a thorough and authoritative summary of information now available. Much material is included, from the laboratories of the Imperial College of Science and Technology, which has not been published elsewhere, and many suggestions are made with the intention of stimulating further research. Interest will naturally be focussed on those sections with which the authors have had so many years intimate contact, such as the chemistry of coal, the phenomena of combustion and the reactions of the blast furnace. At the same time the more technical chapters provide a good picture of the relation of industrial processes to coal itself, although they are inevitably brief in their treatment and rightly exclude any discussion of by-products.

The inclusion of a bibliography at the end of most of the chapters increases the ease of reference to original publications. The printing and binding of the book have been most efficiently carried out, and the illustrations on the whole are excellent; in a few cases (e.g. Figs. 42, 86, and 126) the lettering has been so reduced in size as to be illegible, and the drawings indicating the operation of a water-gas plant are too small to be useful.

R. H. G.

**Die Thermodynamik einheitlicher Stoffe und binärer Gemische, mit Anwendungen auf verschiedene physikalisch-chemische Probleme.**

By Dr. J. J. VAN LAAR. (P. Noordhoff, N.V., Groningen-Batavia, 1935. Pp. viii + 379. Price 12 gld., Bound 13.50 gld.)

Dr. van Laar develops in this treatise, which is divided into two parts as indicated by the title, the general theory of two-phase equilibria of simple substances and binary systems. Both books start with a brief discussion of van der Waals' general equation of state; the first deals with the functional dependence of  $a$  and  $b$  on volume and temperature and, in the second, the dependence on the molar concentration is discussed; the fundamental thermodynamical relations are then introduced. By combining the two theories a detailed analysis of the two-phase equilibria not too near the critical region (gas-liquid) is given. The mode of approach

is typical of the Dutch school of thermodynamics, which carefully correlates the deviations from the ideal laws (e.g. Raoult's law) with the higher terms with  $x^3$  in the molar thermodynamical potentials, which in turn result from the  $a$  and  $b$  of the van der Waals' equation. It is interesting to note how the use of these more general expressions leads to a classification of the vapour pressure curves for binary liquids and of the curves of co-existence for two liquid phases (critical miscibility).

The author has successfully demonstrated the main theorems in a concise way which allows a very clear perception of the theoretical framework. He has added, where it appeared of interest, a critical examination of less exact conceptions (e.g. in relation to Dalton's law) and even of erroneous theoretical representation (e.g. in relation to the osmotic pressure). Furthermore, repeated warnings are given against rash conclusions as to chemical association from deviations from the ideal laws. If association does occur, independent evidence is always absolutely necessary.

In many parts numerical applications of the theoretical deductions are given, in which respect the present work differs from the classic treatise by van der Waals-Kohnstamm. Special mention may also be made of the comprehensive and critical discussion of the melting-, evaporation- and sublimation-curves for all the elements, in which the experimental results are checked.

The theory of strong electrolytes is mentioned mainly in connection with two-phase equilibria. The author favours the Ghosh theory; however, his theoretical objection against the Debye-Hückel theory is not very conclusive, whereas the temperature independence of the Ghosh's "average" distance is not discussed.

In two respects this work might gain in value. The statement that the "constants"  $a$  and  $b$  do vary with volume and temperature is amply justified. It would seem that because of the importance of these quantities a more extensive analysis of their connection with the molecular constants, i.e. the molecular volumes and the molecular attractive and repulsive forces, is desirable. Secondly, the section on specific heats might have been a little more detailed, since modern spectroscopy and statistical theory have given such detailed and accurate information about rotational and vibrational states.

Apart from these two criticisms this treatise is an important addition to the series of monographs of the Dutch School, and needs no further recommendation to all those who are acquainted with the author's earlier works. The volume is excellently printed and produced and contains but few misprints.
